HCAL Commissioning in Proton Collisions at $\sqrt{s}=7$ TeV

The CMS Collaboration

Abstract

We present results on the commissioning and performance of the CMS hadron calorimeters in proton collisions at a center of mass energy of 7 TeV at the Large Hadron Collider. The hadron calorimeter of CMS is divided into sub-systems covering a wide range of pseudo-rapidity utilizing different technologies and electronics. Anomalous background signals, which had been previously observed in data collected in test beam running, have been characterized and studied in collision data. Methods to identify and remove these anomalous signals have been developed and their performance is presented. The hadronic calorimeters are used to trigger the experiment on energy clusters and the trigger performance is discussed. Methods to calibrate the calorimeters using cosmic muons, beam splash events (where the LHC beam is targeted on upstream collimators), and collision data are presented.

1 Introduction

We present results on the commissioning and performance of the CMS hadron calorimeters (HCAL) in proton collisions at a center of mass energy of 7 TeV at the Large Hadron Collider. The hadron calorimeter of CMS is divided into sub-systems covering a wide range of pseudo-rapidity utilizing different technologies and electronics. The HCAL is used to measure hadronic energy deposits and helps determine the missing transverse energy resulting from neutrinos or exotic particles and plays an essential role in searches for new physics. An overview of the HCAL detectors is presented in Section 2. HCAL modules were exposed to test beams in order to establish the energy response to 50 GeV pions. Results from a few channels are then extrapolated to the entire calorimeter. This pre-calibration does not take into account any additional material of the fully assembled CMS detector. Methods to calibrate the calorimeters using cosmic muons, beam splash events (where the LHC beam is targeted on upstream collimators), and collision data are presented in Section 3.

Continuous monitoring is required in order to ensure a high efficiency of data collection that is of a quality suitable for physics analysis. Details of the monitoring tools are presented in Section 6. Output from the monitoring is used to certify the data so that it can be included in physics analysis. The data certification procedure is presented in Section 7.

Anomalous background signals have previously been observed during the exposure of modules to test beams and early commissioning. Algorithms to identify and remove these anomalous signals have been developed and tested with collision data. Details are presented in Section 8. The algorithms exploit the properties of the anomalous signals, such as energy isolation and timing. In order to take full advantage of these properties it is essential to have a good understanding of the pulse shape and well aligned channels.

The hadronic calorimeters are used to trigger the experiment on energy clusters and missing E_T . An overview of the HCAL trigger is presented in Section 5.

2 HCAL Description

The CMS calorimeter is composed of an inner electromagnetic calorimeter (ECAL) surrounded by a hadronic calorimeter (HCAL) enclosed within a solenoid operating at 3.8 Tesla. The ECAL consists of a barrel region (EB) covering the pseudorapidity range of $1.5 < |\eta|$ and an endcap section (EE) covering $1.4 < |\eta| < 3.0$. The HCAL barrel (HB) covers the region $|\eta| < 1.3$ and consists of 36 azimuthal wedges assembled into two half-barrels (HB+ and HB-). The Hadronic endcap calorimeter (HE) covers the pseudo rapidity range $1.3 < |\eta| < 3$. The hadronic forward calorimeter (HF) extends the coverage $3.0 < |\eta| < 5.0$. Additional scintillators (HO) are located outside of the solenoid and act as “tail catchers” effectively increasing the thickness of the calorimeter in the central pseudo rapidity region. Figure 1 is an elevation view of the CMS detector showing the HCAL components with lines of constant pseudo rapidity overlaid.

The HB is a sampling calorimeter consisting of alternating plates of brass absorber and scintillator tiles embedded with wavelength shifting (WLS) fibers. The WLS fibers are spliced to clear fibers which direct the light to an optical decoder unit (ODU). The ODU arranges the fibers into readout towers covering an area of 0.087×0.087 in $\eta - \phi$ and direct the light from each tower to separate channels of a hybrid photo diode (HPD) which can operate in a high magnetic field. Each HPD has 18 channels of readout.

Analog-to-digital converters (ADCs) digitize the signals from the calorimeter for readout. Charge is integrated over each 25 ns time sample separately and a total of ten time samples are recorded.

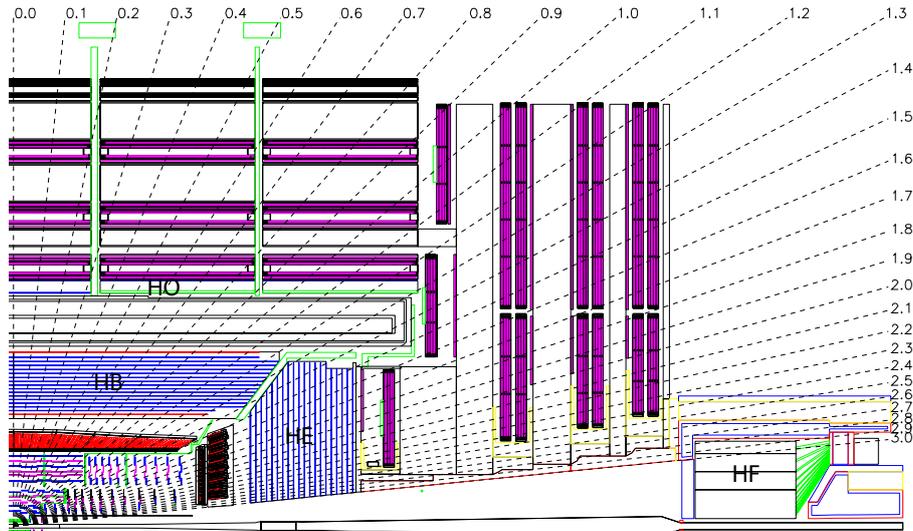

Figure 1: An elevation view of the CMS detector showing the HCAL subsystems (HB, HE, HO, and HF). Lines of constant pseudo-rapidity are shown as the dashed lines in the figure.

45 Signals from 4 HPDs in HB/HE (or 24 PMTs in HF) are digitized within a single read-out box
 46 (RBX). A more detailed description of the CMS calorimetry system can be found in [1]. Dis-
 47 cussions of the design and performance of the HB, HE, and HF sub-detectors may be found
 48 in [2]-[3].

49 The HF sub-detector is a Cerenkov light detector made up of quartz fibers embedded within
 50 a 165-cm-long steel absorber. There are two types of fibers within the HF: “long” fibers which
 51 span the length of HF, and “short” fibers which begin 22 cm into the detector. Differences
 52 between signals read out from the long and short fibers can be used to distinguish between
 53 electrons or photons and hadrons. Photomultiplier tubes (PMTs) connected to the fibers via
 54 light guides convert detected light to electrical signals.

55 Energy is reconstructed from the digitized charge measurements. In HB, HE, and HO 4 time
 56 samples are summed together. The signal in HF is very fast and has a width of about 10ns
 57 which is mostly contained within one 25ns time sample. Individual channels are combined
 58 into a projective tower structure which combines information from ECAL and HCAL. In order
 59 to save disk space, the raw digitized data is dropped from the event record and most physics
 60 objects which use calorimeter information are then derived from the CaloTower objects.

61 3 Calibration

62 Calorimeter modules were exposed to test beams of pions with known energies in order to
 63 obtain the measured response at several energies. The energy scale for 50 GeV pions was
 64 then extrapolated to the remaining channels of the entire calorimeter using Co60 radioactive
 65 sources. Details of the test beam analysis and the wiresourcing can be found in Ref. [4]. This
 66 procedure does not take into account any addition dead material of the fully assembled CMS
 67 detector.

68 The calibration of HCAL was further improved using cosmic muons and so called “beam
 69 splash” events. Beam splash refers to data collected when the proton beam was intentionally
 70 steered into collimators upstream of the CMS detector in order to produce a spray of muons.
 71 Both methods provided valuable information that allowed us to equalize the detector response

72 in the +/- sides of HB, and derive relative channel-to-channel corrections in HB and HE. Splash
 73 events were also used in the identification of a few channels that had a relatively large deviation
 74 in the response from adjacent cells. More details can be found in Ref. [5].

75 An example of a ϕ -profile of the energy deposited in HB from splash events is shown in the left
 76 plot of Figure 2. We expect smooth energy distribution and miscalibrated channels are iden-
 77 tified as having energy measurement that deviate significantly from the trend in their vicinity.
 78 The same arguments are also valid for the energy distributions in z which is shown in the right
 79 plot of Figure 2. Combining the information from the ϕ - and z -distributions allows us to equal-
 80 ize the response over the entire HB with the exception of cells near the outer boundaries. A
 81 similar procedure was applied to HE.

Figure 2: The left plot shows the ϕ -profile of the energy deposition in HB by splash events
 while the right plot shows the z -profile.

82 These techniques combined with the source calibration provide our initial measure of the ab-
 83 solute energy response of the HCAL sub-detectors and is referred to as the precalibration con-
 84 dition. Precalibration does not fully account for all the dead material that particles originating
 85 from the interaction point will traverse. Additional calibration methods using collision data
 86 are needed. It is also necessary to continuously monitor the response of HCAL to compensate
 87 for aging effects.

88 A calibration workflow was developed that includes several techniques covering HB, HE and
 89 HF. It was targeted at early data calibrations that could be performed with tens of pb^{-1} . The
 90 workflow includes the following steps; first an azimuthal symmetry correction is applied to
 91 equalize the response in HB, HE, and HF within rings of constant η ; next, an absolute energy
 92 correction is determined using isolated charged particles for HB and part of HE; finally, the
 93 absolute response is extended to the forward region using dijet and photon-jet events. The
 94 calibration steps are not completely independent and the results of each step are used in the
 95 subsequent one. These corrections are derived with respect to the “precalibrated” conditions.

96 Due to the complex structure of the hadronic calorimeter, its large coverage and different over-
 97 lapping regions with other detector systems used for the calibration it is necessary to use mul-
 98 tiple techniques and data samples. Additional complications arise from the non-linearity of the
 99 HCAL energy response and the relatively large lateral size of hadronic showers and it is not
 100 possible to set an absolute scale that is valid for all energies of incident hadrons. We define the
 101 target absolute scale to correspond to $E_{had} / p_{trk}=1$ for charged hadrons with momentum 50 GeV
 102 that do not interact in the electromagnetic calorimeter where (E_{had} is the measured energy in
 103 a tower cluster described later in the text. The criteria for this choice is that the energy is in a
 104 region where the calorimeter response as a function of energy is slowly changing and it can be
 105 set and tested directly.

106 The first step of HCAL calibration with collisions data is to equalize the response in ϕ for
 107 each η ring. The procedure takes advantage of the azimuthal symmetry of the detector and
 108 the corresponding ϕ -symmetric energy deposition from minimum bias (MinBias) events. The
 109 intercalibration is performed by comparing the average energy deposition in a calorimeter cell
 110 to the mean of the average energy distributions in the entire η -ring (cells with $i\eta=const$). One
 111 of the main challenges is the large channel to channel noise fluctuations and relatively small
 112 signal in HB and HE.

113 Isolated charged hadrons are used to set the absolute energy scale of the hadronic calorimeter
 114 in the region with tracking coverage. Tracks with momenta in the range $40 < p < 60$ GeV are

115 selected to correspond with the energy scale set in the test beam. Requiring that the track is iso-
 116 lated prevents overlapping energy depositions from other particles. Since charged hadrons can
 117 often deposit a substantial part of their energy in the electromagnetic calorimeter (ECAL), we
 118 select only tracks that behave like minimum ionizing particles (MIPs) in the ECAL by requiring
 119 their energy deposition in ECAL to be below a threshold.

120 The tracks are selected based on their quality, isolation from charged particles in the tracker, iso-
 121 lation from neutral particles in ECAL, and their energy deposition in ECAL. Energy in HCAL
 122 is collected in a cluster defined by a cone around the direction of the track at the HCAL surface.
 123 The selections are optimized to ensure good energy containment in the cluster, low energy con-
 124 tamination from neighboring tracks, and sufficiently high selection efficiency under realistic
 125 data-taking scenarios. Our current estimation is that we need 5-10 pb^{-1} of data collected using
 126 a dedicated trigger to obtain η -dependent response corrections in HB and HE.

127 Di-jet balancing and photon-jet balancing were proposed for calibrating HF and the HE region
 128 not covered by the tracking system. This calibration procedure is performed after the phi sym-
 129 metry corrections are available and after HB is fully calibrated. The procedures are similar to
 130 the ones used for jet energy scale determination. The difference is that the derived corrections
 131 should equalize the response on a cell-by-cell basis. This poses a significant challenge and the
 132 procedures are still under development.

133 Here we listed only the basic set approaches that are going to be used with early data. There are a
 134 number of other techniques that are under development and showing promising results.

135 3.1 First Results with Collision Data

136 The full calibration of HCAL with collision data requires the collection of large samples of
 137 events. Until we have sufficient statistics we can use the existing data to test the procedures
 138 and to get a first look at the HCAL response by using tracks with a lower momenta range.
 139 Samples with $p_{trk} > 5$ GeV tracks were selected from MinBias events to check the relative
 140 response of different detector systems and the quality of the MC simulation.

141 [description of the early studies, at this time put only the plots that we want to show]

142 Figure 3 shows the distribution of E/p_{trk} for isolated tracks with a momentum range of $9 < p <$
 143 11 GeV.

144 [responses in +/- sides, ratios]

145 4 HCAL Timing

146 4.1 Timing in HB and HE

147 Timing and synchronization methods for the HCAL barrel and endcap from test beams and
 148 beam splash events were previously reported in [12]. With the advent of LHC collisions at CMS
 149 came the first opportunity to assess the effectiveness of this prior campaign for timing and
 150 synchronization of collisional signals. The difficulty in synchronizing the barrel and endcap
 151 channels with collision data is the reduced number of high-energy, well-timed events as $|\eta|$
 152 goes to zero.

153 A study was undertaken to assess the performance of front-end channel phase settings in the
 154 barrel and endcap that were derived from so-called "beam splash" events in late 2009. Collision
 155 events were selected by requiring a high-quality reconstructed primary vertex for the event.
 156 Gaussian fits were applied to each channel, and the means of the fits are plotted. The resulting

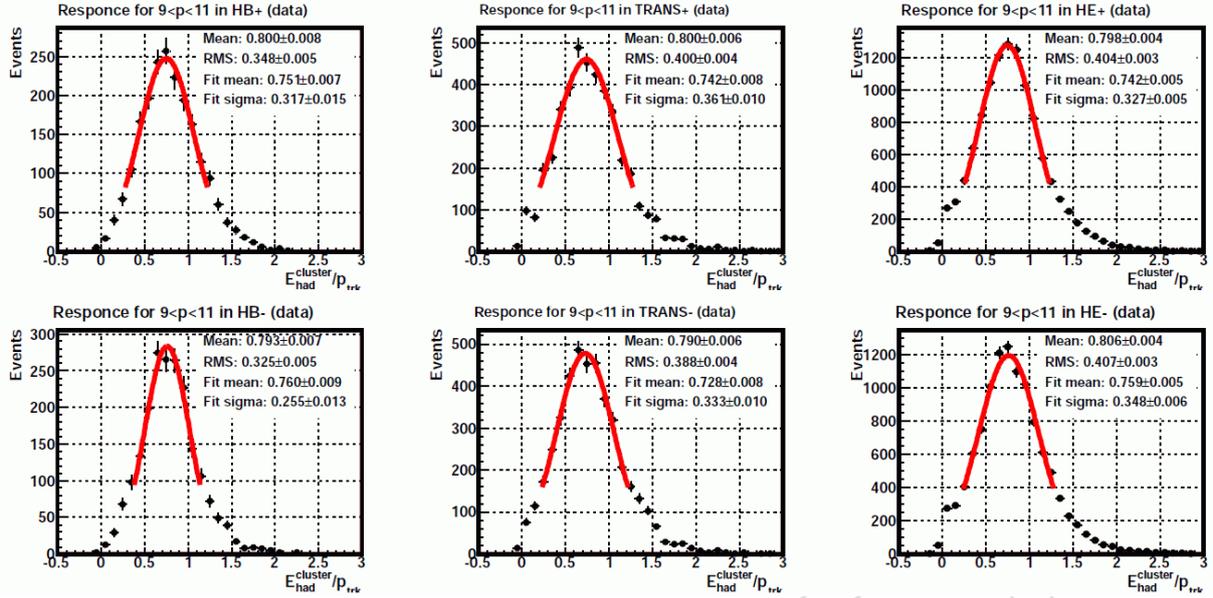

Figure 3: Example response profiles for tracks with momenta $9.0 < p_{trk} < 11.0$ GeV in the positive and negative sides of HB, HE, and the “transition” region. The solid lines represent the results of Gaussian fits.

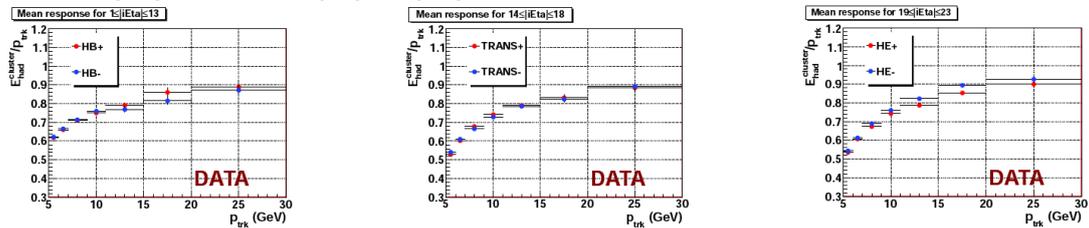

Figure 4: Comparison of the response in the positive and negative sides of the hadron calorimeter. The left, right, and middle column show the results for tracks in HB, HE, and the “transition” region as described in the text. The top row of plots show the measured response as a function of track momentum, while the lower plots display the ratios of the response in the positive side to the response in the negative side.

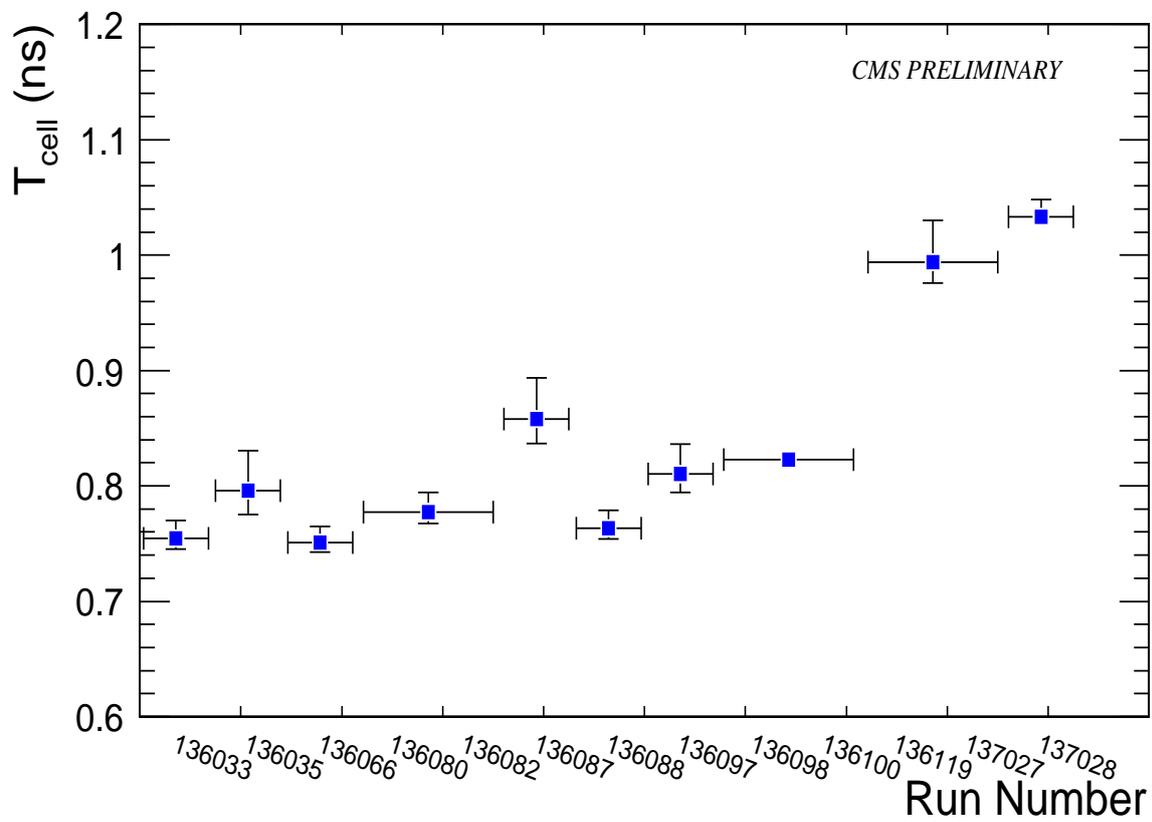

Figure 6: Timing stability in the barrel and endcap combined, as a function of run number. A 20 GeV minimum cell energy threshold was applied.

htbp

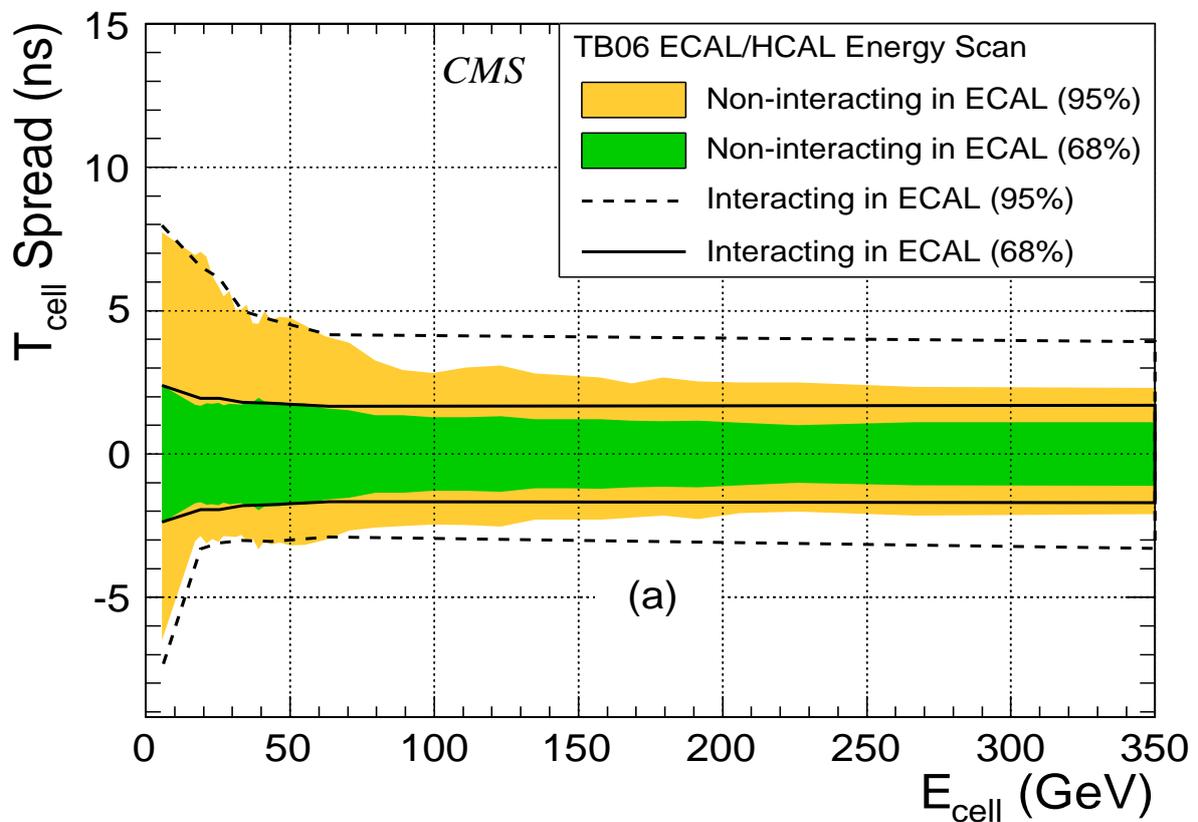

Figure 7: *NB: PLOT TO BE UPDATED.* Timing resolution as a function of energy measured during test beam runs in 2006, showing the consistency of time reconstruction for particles that begin showering in the ECAL (lines) and those that do not (areas).

htbp

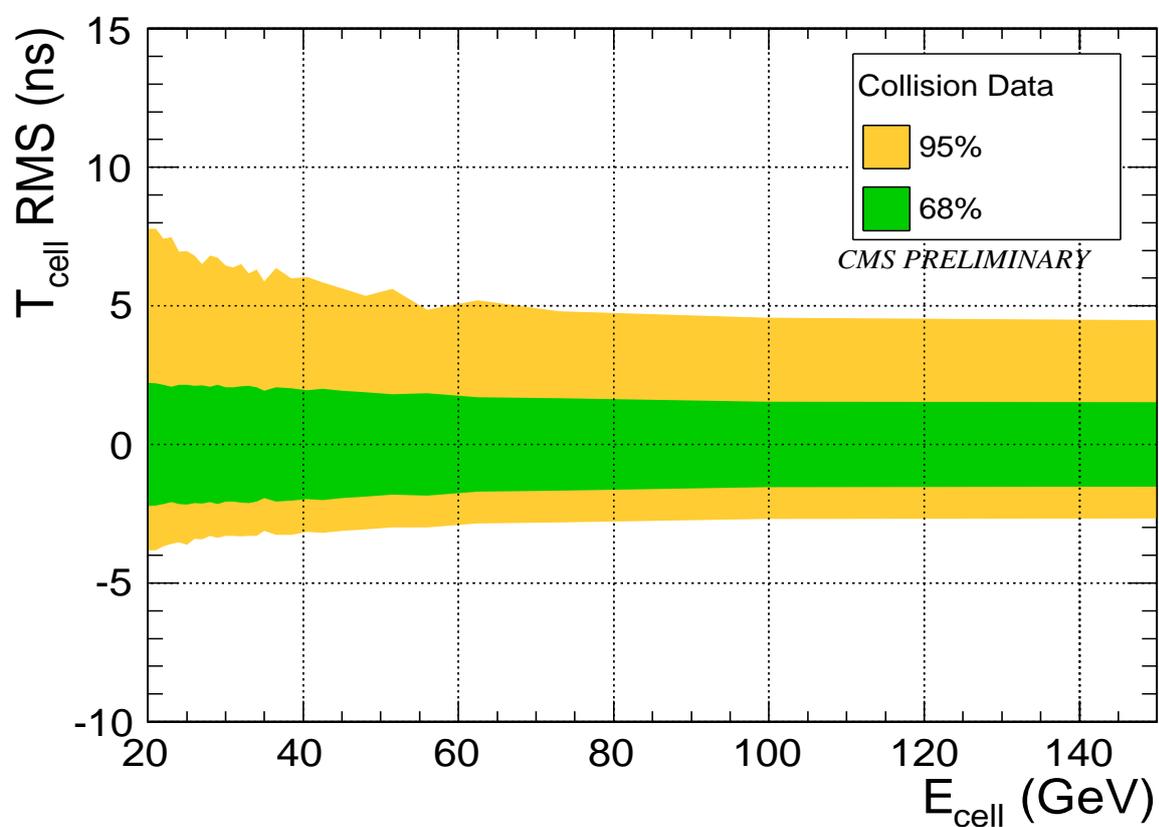

Figure 8: Timing resolution as a function of energy measured during 3.5 TeV/beam collision runs in 2010. A 20 GeV minimum cell energy threshold was applied.

157 distribution of mean channel timing is shown in Figure 5. These corrections are then applied
158 offline to each calorimetric timing measurement in order to improve the channel alignment and
159 to define a nominal “ $t=0$ ” for physics analysis, as evidenced by the Figures 6 and 8. Efforts to
160 improve the channel alignment are continuing, particular as more data are collected.

161 Figure 6 exhibits the stability of timing in the barrel and endcap over several of the data runs
162 taken so far. Figures 7 and 8 compare the timing resolutions as a function of cell energy as mea-
163 sured in test beams and in collision data. The additional spread in collision data is attributed
164 to ion feedback and residual channel misalignment.

165 4.2 Timing in HF

166 In contrast to the barrel and endcap, the arrival time of signals from the HCAL Forward detec-
167 tor cells are much more difficult measure. This is because, due to the high expected occupancy,
168 the forward detector was designed to yield faster signals. Depending on the phase of the sam-
169 ple clock with respect to LHC collisions, well over 90% of the signal energy can be contained in
170 a single time sample; in fact, the forward detector channels were phase aligned to accomplish
171 exactly this result. This phase alignment is described below. The purpose was to avoid the
172 generation of “pre-triggers” from the forward channels.

173 As long as the trigger timing is synchronized with the rest of CMS, there would be little else
174 to motivate the measurement of HF signal times more precisely than a time sample. The ex-
175 ception comes from PMT window interactions. Since all channels are calibrated for fiber light
176 amplitudes, these interactions generate artificially high signal energies, thereby inducing fake
177 missing transverse energy. The use of precise timing represented one potential handle for the
178 rejection of this noise.

179 At the same time the arrival of collisions at the LHC represented the first opportunity to time-
180 align all of the HF channels in-situ. Other portions of the HCAL had been aligned previously
181 with so-called beam splash events, but the position and geometry of the HF cells, as well as the
182 high flux of muons hitting the PMT windows and fiber bundles, prohibited the use of splash
183 data for such a purpose with HF.

184 An HF scan campaign was therefore undertaken at the start of 7 TeV beam commissioning,
185 to time-align the channels and to investigate ways to leverage timing as a means of PMT in-
186 teraction rejection. Since the precise timing depends on the relative energy sharing between
187 adjacent time samples, it would be necessary to find the per-channel sample clock phase set-
188 tings that would place the nominal signal at the boundary between two adjacent time samples,
189 represented by an even 50-50 energy sharing.

190 Data were acquired in intervals of 15-20 minutes, time enough to collect sufficient statistics
191 at each phase setting. Then data acquisition was paused to load new settings to the front-
192 end electronics. Online Data Quality Monitoring was used to estimate when optimal energy
193 sharing was achieved for most channels. The data were then analyzed offline to determine for
194 each channel at which phase setting the 50-50 sharing crossover occurred. This point represents
195 the point in phase space with maximally sensitive time measurement capability. Setting all
196 channels at their respective maximal sensitivity simultaneously synchronizes the channels.

197 One question to be answered by the phase scan was whether the magnitude of the jitter in
198 signal times and PMT interaction times is too large to resolve them effectively. The next step
199 was therefore to apply the alignment settings and acquire data at this setting with maximal
200 timing sensitivity, to measure the signal jitter. It was determined that the signal jittered with a
201 spread of ± 2 ns, which is small enough to adequately resolve PMT interactions in time.

htbp

Figure 9: Timing distributions in HF for both collision events and PMT interactions.

htbp

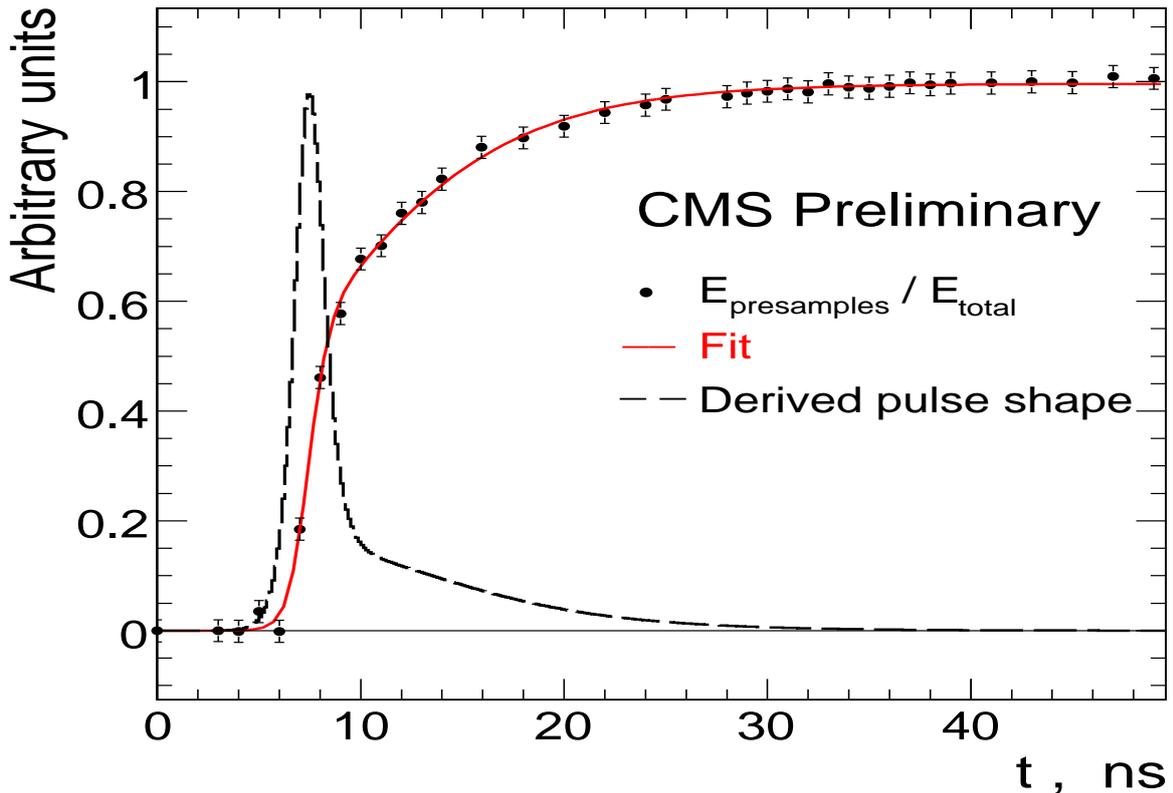

Figure 10: Pulse shape reconstruction in HF as a result of time scan measurements taken during the first 3.5 TeV collision runs. The data points represent the average fraction of the total energy within the ten-sample window that is contained in the first n samples, where $n=4$ for the first 25 ns and $n=5$ in the second 25 ns, as a function of front-end phase setting. The fit curve then represents the integrated pulse shape, and the dashed curve represents the differentiated pulse shape.

202 Since 50-50 sharing also represented an unacceptable perturbation of the trigger timing, the
 203 next step was to apply a global shift to the settings so that the signal for all channels occurred,
 204 with sufficient safety margin, just after the time sample boundary, while simultaneously re-
 205 maining aligned. PMT window interactions are known to occur earlier in time, since the light
 206 from particle showers propagate in the quartz fibers at reduced speed. Setting the global phase
 207 in this way preserved the trigger while also affording the potential capability to detect and
 208 reject PMT interactions.

209 This intensive timing and synchronization effort for HF also provided the opportunity to assess
 210 the effectiveness of the precise time reconstruction algorithm for collisional signals in HF. This
 211 algorithm starts in the same way as that reported for the barrel and endcap in [12], with a first

212 order time estimate from a center-of-gravity technique using the three samples centered on the
 213 peak,

$$\text{Weighted peak bin} = \left[\frac{(p-1)A_{p-1} + pA_p + (p+1)A_{p+1}}{A_{p-1} + A_p + A_{p+1}} \right] \times C, \quad (1)$$

214 where A_i represents the amplitude of an arbitrary time sample i , and p is the value of i such
 215 that A_p is maximum over the set of samples. In the case of multiple samples with the same am-
 216 plitude, the earliest one is picked. The constant C is an amplitude-independent normalization
 217 constant that rescales the first order estimate to a range from zero to one. The weighted peak
 218 bin is then used to determine a second order correction that compensates for the asymmetry of
 219 the pulse shape, yielding the phase of the signal within the peak time sample.

220 The second order correction derives from a functional form of the pulse that was fit to data; at
 221 the start of the scan campaign the pulse was derived from test beam data taken in 2004. Since
 222 the actual front-end phase setting represented an independent truth time, it was possible to re-
 223 derive the pulse shape seen with collisions (Fig. 10). The correction function derived from the
 224 new fit was then used to investigate other timing effects and uses; one such additional effect
 225 was the determination of energy dependence on timing at low energies. Efforts are ongoing to
 226 optimize the algorithm for HF and to determine the limitations of the timing algorithm across
 227 all phase settings.

228 5 HCAL Trigger Performance

229 5.1 HCAL Triggers

230 The HCAL trigger is based on the HCAL calorimeter towers. The calorimeter trigger towers in
 231 HB/HE are typically comprised of physical calorimeter towers ganged together in depth. The
 232 exception to this rule are the $\Delta\phi = 10^\circ$ HE calorimeter towers, which are split in two trigger
 233 towers in ϕ , each of which is assigned one-half of the calorimeter tower energy, and the HF
 234 trigger towers.

235 The first 20 trigger towers in HB/HE up have constant $\Delta\eta \times \Delta\phi = 0.087 \times 0.087$. While the
 236 azimuthal granularity stays the same in the inner part of HE, the η size starts increasing
 237 starting with tower 21 and reaches 0.35 for the last HE trigger tower 28. Altogether there are
 238 $17 \times 72 = 1224$ trigger towers in each half of the HB, and $11 \times 72 = 792$ trigger towers in each
 239 HE.

240 Each HF trigger tower is formed from 6 physical HF towers, with the long and short fibers
 241 ganged together. Thus, each HF trigger tower consists of 12 individual calorimeter inputs.
 242 There are 13 η rings of calorimeter towers in the HF mapped to 4 trigger towers in η (29-
 243 32). The outermost 11 of them have ϕ segmentation of 0.175 radian, and for the two innermost
 244 one the segmentation is twice as coarse. The three outermost trigger towers in η combine two
 245 adjacent towers in three adjacent η rings. The innermost trigger tower contains two adjacent ϕ
 246 towers in the rings 10 and 11, and one tower each from rings 12 and 13. Thus, all the HF trigger
 247 towers have the same azimuthal size of 0.349 radian and the same $\eta = 0.5$ size. Altogether,
 248 each HF contains 72 trigger towers.

249 The HCAL trigger primitives are formed for each trigger tower by combining the informa-
 250 tion from individual calorimeter towers. Since the HCAL QIE's use 7-bit non-linear ADC's
 251 with several ranges, the energy reported by the QIE is first linearized as a 10-bit word, via a

252 dedicated look-up table (LUT). The linearization depends on several parameters, such as gain,
253 conversion from the collected charge in fC to the ADC counts, and the pedestal. Since in
254 general these parameters vary from one calorimeter channel to another, each input channel is
255 linearized with an individual LUT, automatically generated from the database containing all
256 the above information. These LUT's essentially remove the channel-to-channel variations and
257 make linearized output to look the same for each group of calorimeter towers using the same
258 type of LUT. In the HB/HE the linearized output for each calorimeter tower is proportional to
259 the energy registered in this tower. This is the optimum linearization, as it allows to suppress
260 noise (constant in energy) uniformly over the large η range spanned by the calorimeter. Since
261 the conversion from energy to transverse energy, E_T , the quantity typically used in the trigger,
262 depends on the position of the readout channel in the calorimeter, it is impossible to achieve
263 both high resolution and large dynamic range in E_T with the single set of LUT's. Thus, the
264 HB/HE is divided in three ranges in η , each served by a different LUT: towers 1-20 in η have
265 the LUT that linearizes energy with the highest granularity, with the least significant bit (LSB)
266 corresponding to ~ 0.2 GeV; towers 21-26 have twice as coarse granularity and expanded dy-
267 namic range in energy; towers 27-28 have 5 times as coarse granularity as in HB and even more
268 expanded dynamic range. as a result, we achieve the individual readout channel saturation
269 above $E_T = 64$ GeV over the entire calorimeter and as the same time keep the LSB below the
270 typical noise level in most of the HB/HE.

271 Since the pulse in the HB/HE spans more than one time crossing, the trigger primitive (TP)
272 is more complicated than a simple sum of several linearized calorimeter readout channel en-
273 ergies. One also must perform a temporal sum over the two adjacent bunch crossings, which
274 contain about 95% of the calorimeter pulse energy, and look for peaks in the time sequence, in-
275 dicating a signal. The peak-finding is done by requiring the running sum of energy in a certain
276 bunch crossing and the one after it to exceed that in the previous one and to be at least as large
277 as in the subsequent bunch crossing. If the condition is satisfied, a non-zero trigger primitive
278 is generated for the bunch crossing corresponding to the leading edge of the pulse; otherwise
279 it is set to zero. Consequently, most of the TP's in each event are identical to zero, which allows
280 for efficient trigger data compression.

281 In addition to the TP generation in HF, a fine-grain bit is also generated if at least one of the six
282 sums over the transverse energies in the long and short fibers of the same HF tower in any HF
283 trigger tower is greater or equal to a certain threshold (currently set to 0.125 GeV). This bit is
284 used for minbias trigger generation.

285 5.2 HCAL Trigger Primitive Validation

286 Since HCAL trigger is fully digital, it is possible to emulate its performance precisely. In order
287 to validate the trigger, we run the emulation on the trigger data and compare its results with
288 the actual trigger primitives generated. If everything works fine, the two must agree exactly.
289 The comparison of the emulator output and actual TP's for laser calibration runs are shown in
290 Fig. 11. As expected, we have perfect agreement between the hardware performance and the
291 emulation.

292 It is somewhat harder to validate TP's in collision data, as it is zero-suppressed (ZS). In case of
293 zero suppression the information available for the trigger emulator misses towers with energies
294 below the threshold. The comparison of the emulator output and actual TP's in collision data
295 are shown in Fig. 12. As expected, the correlation is not perfect due to ZS, but still very good.

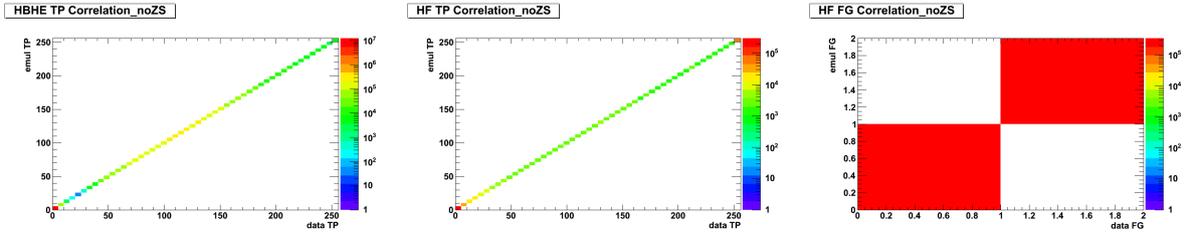

Figure 11: Results of the emulation vs. generated trigger primitives in: left — HB/HE TP's; center — HF TP's; right — HF FG bit. The values on the x -axis correspond to results of emulation; the values on the y -axis are TP's generated by the hardware. Results are based on calibration runs 136658 (HB/HE) and 136869 (HF).

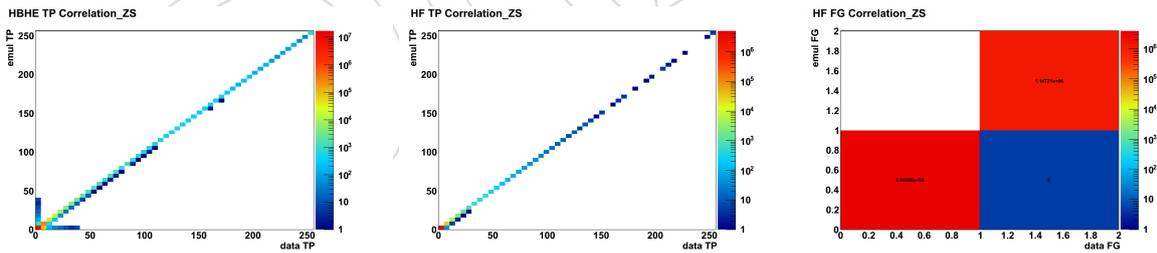

Figure 12: Results of the emulation vs. generated trigger primitives in: left — HB/HE TP's; center — HF TP's; right — HF FG bit. The values on the x -axis correspond to results of emulation; the values on the y -axis are TP's generated by the hardware. Results are based on 7 TeV collision run 137027 with zero-suppression enabled.

6 Detector and Data Quality Monitoring

Data to monitor the performance of Hcal are collected under different conditions. Special runs are taken between stores when no beam is circulating in order to monitor noise rates and detector response. A fraction of the collision data is collected in real time and monitored as part of the Online DQM. Additional online data is read out during orbit gaps in ongoing runs to monitor detector stability. Finally, as finished runs are processed and reconstruction, offline DQM is run on the results in order to determine the Data Certification status for the runs.

6.1 Data Quality Monitoring Tasks

The Hcal DQM software provides a number of checks on data quality for each channel in the detector. Any channel that fails even one of these tests is considered problematic, and the overall Data Certification status value is lowered accordingly for each such channel found. Testing modules that are available within the Hcal DQM include:

- Raw Data Test – this performs checks on the format of the raw data received from Hcal. Corrupted data from the Hcal front ends are detected by this test.
- Digi Test – this checks the integrity of the digitized outputs (“digis”) constructed from the raw data.
- Dead Cell Test – this checks for channels that never or rarely report valid digis or reconstructed hits (RecHits).
- Hot Cell Test – this checks for channels that report otherwise valid data, but which record larger-than-expected energies in a significant fraction of events.
- Trigger Primitive Test – this compares the Hcal trigger primitives reported by the trigger framework against expected primitives as emulated from Hcal input data.
- HF Luminosity Test – this performs additional data quality tests for those channels in HF used for luminosity monitoring.
- Pedestal Test – this compares the measured background from electronics noise fluctuations for each Hcal channel during a run to the expected level of noise.
- Laser Test – this checks the response of Hcal channels to input signals of known energy, as provided by the laser calibration system.

Each of the above tests produces a set of four histograms, indicating the number and rate of problem channels in each Hcal depth (see Figure 13). The results from these histograms are combined over all tests to form an overall “reportSummaryMap” indicating the overall health of the Hcal system. This map is used for quick monitoring of the Hcal system by DQM shifters and for a first determination of the data certification status for the run.

Additional diagnostic histograms that don’t feed the reportSummaryMap are also produced by the DQM. These include plots of the energy and timing distributions of reconstructed Hcal hits, monitoring plots of noise rates during the run, and checks on the zero suppression algorithms used by Hcal. Some plots are trigger dependent, filling only when a Minimum Bias or Hcal coincidence trigger fires, and are thus useful indicators of the overall beam status.

The Hcal DQM is set up within a flexible framework, so that additional plots can be easily added upon request. However, constraints on the speed, memory usage, and size of the DQM output limits the total number of histograms that may be added to the monitoring system.

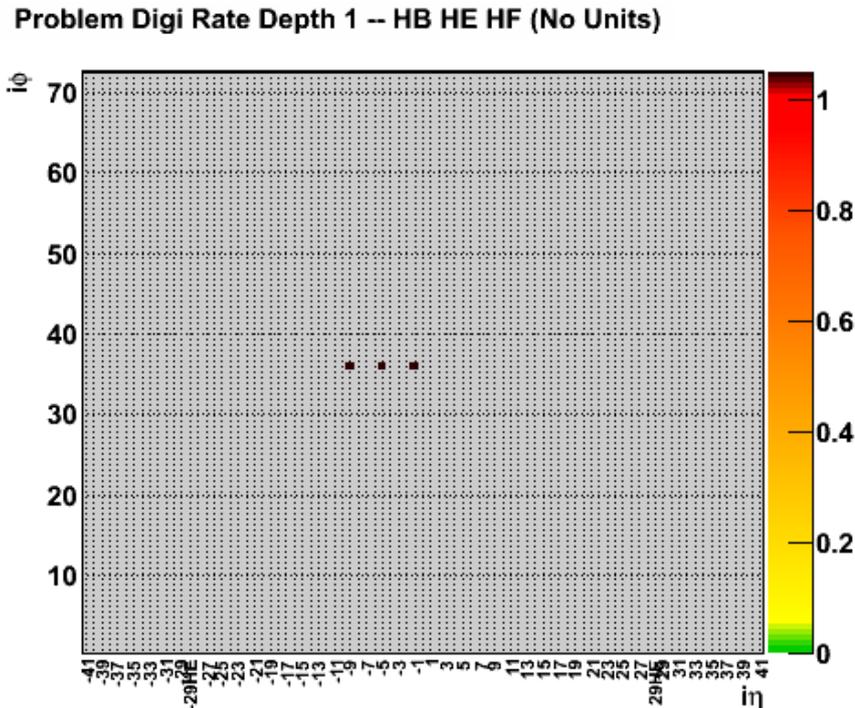

Figure 13: Problem channels detected by the Hcal DQM Digi Monitor task in run 137022. The depth 1 plot shows three known dead HB channels from a broken fiber.

337 6.2 Online Data Quality Monitoring

338 The online Data Quality monitoring system receives a prescaled set of data from the “all”
 339 stream and from the calibration stream. (Calibration stream data includes data from pedestal
 340 and laser events recorded during orbit gaps.) The Hcal DQM runs on this subset of events,
 341 and produces the monitoring and diagnostic histograms described above. Shifters are able to
 342 observe these plots in real time, and problems observed in the DQM are immediately reported
 343 to Hcal experts. This allows to quick responses to sudden changes in the detector during the
 344 run (e.g., RBXes that stop sending data, channels that suddenly appear noisy, etc.).

345 Because the online DQM stream only receives a subset of all calibration events, many laser
 346 pulse calibration events are not seen by the standard Hcal DQM. It was found that the rate of
 347 laser events received in the DQM stream would not be large enough to provide meaningful
 348 real-time monitoring of the Hcal detector response. Increasing the rate of laser events into the
 349 online stream would mean increasing the number of laser pulses beyond the allowed pulse
 350 budget and decreasing the fraction of online DQM events from actual collision events. Neither
 351 of these outcomes was desirable, so instead a separate data stream was set up that accepts only
 352 unrescaled Hcal calibration events.

353 This calibration data stream feeds a duplicate online Hcal DQM process, referred to as “Hcal-
 354 Calib”. This process monitors the stability of each channel’s pedestal and laser response during
 355 global runs. The pedestal and laser responses may also be checked during special “local” runs
 356 when Hcal is not included in global data taking. The HcalCalib DQM runs in a standalone
 357 mode during these local runs, and produces the same monitoring plots that are produced dur-
 358 ing global runs. The HcalCalib DQM also produces additional monitoring plots from local LED
 359 calibration runs.

6.3 Offline Data Quality Monitoring

The offline DQM runs the same Hcal DQM framework as the online DQM. However, a few tests that are run in the online DQM are disabled in offline DQM. The offline DQM does not have access to emulated Hcal trigger primitives or to Hcal calibration data. Thus, the monitoring of trigger primitives, pedestals, and laser data is not performed on offline data.

Offline DQM runs both on the “express” stream data and the full dataset as they become available. Extra monitoring of Hcal noise that is not done in online DQM is performed on these data due to the higher statistics available in offline DQM. The express stream contains a larger fraction of high-energy jet triggers than either the online stream or the all stream, and thus contained a biased contribution from Hcal HPD/RBX noise. Care must be taken when using the express stream for data certification not to mark the Hcal subdetectors as bad

7 Data Certification

Determining the usable fraction of data is essential for any experiment. For large scale experiments a well-defined data certification process is needed that combines information from each sub-detector and physics object group. Since a stable run could take hours, it is important to have the certification information at a fine grained level. Data certification identifies impermanent or new problems in hardware, software and conditions. The goal is to have the significant fraction of the certification performed in an automated way to be able to cope with very long periods of data taking and to be able to identify the *bad* portions of each dataset quickly. This should also allow the user to select and use only the *good* parts of the data in an easy fashion. Certification needs to be able to determine ‘good’ portion of each dataset at the lumi-section level ¹ (i.e. 23 seconds). There are several sources of information that feeds data certification and each piece of information must be judged and the quality of the data has to be determined. DQM (*Data Quality Monitoring*), *run-registry*, automated run certification information from DCS (*Detector Slow Controls*), DAQ (*Data Acquisition*) and DQM, and information from operation and detector performance experts need to be taken into account in this process. The details of the CMS central DQM, *run-registry* and certification can be found in the references [6–8]. The overall HCAL data certification workflow is shown in Figure 14 .

Run-registry is a database that contains information on all *significant* runs that might be used by physics analyses. The information kept in the *run-registry database* is accessible through a web interface which also allows to enter quality flags and production of *certified* run and lumi-section lists. Run registry contains separate quality flags obtained from manual and automated certification for each data set. Manual quality flags of the *run-registry* are provided by the central online shifter at P5 and the offline shifter at the CMS Center at CERN Meyrin site. The automatic run certification combines the results from DCS, DAQ, and DQM in which each component is assessed independently from each other. The results of DQM are summarized in the so-called Report Summary Values which are formed from the hot cells, dead cells, data format errors, bad digis, pedestal and laser monitors. The report summary values show the goodness of each subdetector of HCAL; HB, HE, HF, HO, HO0, HO12. HCAL is considered *good* if the fraction of cells without problems is greater than a predetermined value. The DAQ, DCS, and DQM, and the certification results combining these three are written to run-registry and to DQM root files. The DAQ information at this stage is irrelevant to HCAL certification since it is duplicated in DQM summary values.

¹It is also important to note that some portion of data is filtered at the event or channel level during reconstruction (see Section 7).

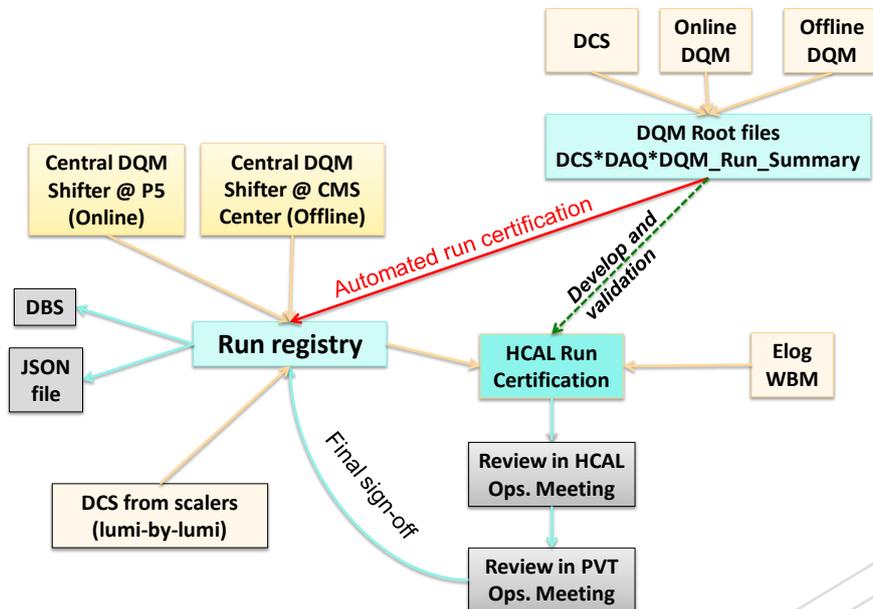

Figure 14: Overview of DQM and manual and automated run certification framework.

403 DCS information could not be used extensively until now, however, with the recent develop-
 404 ments, it started to become a part of the data certification. Run registry currently contains a list of
 405 bad lumi sections for hardware partitions of each sub-detector. Any hardware error reported
 406 from the DCS system causes the corresponding lumi section to be *bad* for the corresponding
 407 sub-detector partition. Also, a procedure is setup to automatically record high-voltage val-
 408 ues that deviate beyond preset tolerances, correlate them with corresponding run numbers
 409 and lumi sections, and write them to database tables. This information is transferred to the
 410 offline database by automatically every hour. During the harvesting stage, offline DQM will
 411 read these values from the offline database, and combine the decisions for each subdetector of
 412 HCAL with report summary values and DAQ values and produce a single certification value
 413 for each subdetector per lumi section.

414 7.1 HCAL Run Certification Procedure

415 *Status values* are taken from the HCAL DQM results, and reflect the fraction of channels in
 416 each subdetector that report valid data. The following checks must all be passed for an HCAL
 417 channel to be considered valid:

- 418 • Reconstruction checks: Raw data from the channel must be able to be *unpacked* into
 419 *reconstructed hits* without encountering errors in timing, size, or hardware perfor-
 420 mance;
- 421 • Dead cell check: *Reconstructed hits* from the channel must be present in at least a
 422 minimum fraction of overall events;
- 423 • Hot cell check: The number of *reconstructed hits* above a threshold energy from the
 424 channel must be less than a given fraction of total events, and the average energy
 425 seen in ‘quiet’ (orbit gap) events must be within tolerances.

426 There are three categories of flags which are used as quality flags; *good*, *bad*, *excluded*. The

427 HCAL quality flag is set to 'GOOD' if the following conditions for the four HCAL subdetectors
428 (HB,HE,HO0,HF) are met: HB status > 0.98 , HE status > 0.98 , HO0 status > 0.95 , and HF
429 status > 0.98 . For some special cases, a run is still usable if its quality flag is not set to *good*. For
430 example, if a run is marked *bad* due to HF problems, that run would still be usable by analyses
431 that do not use HF or depend on missing transverse energy. Automatic quality flags allow
432 separate judgments to be made and stored for each HCAL sub-detector. When HCAL is not in
433 readout, the run is marked as *excluded*.

434 GOOD status criteria might change in time. Certification criteria are entered manually in
435 the central *HcalDataValidation twiki page*[10] and run-registry database since the overall crite-
436 ria changes very rarely. However, if the criteria needs to be changed more frequently, then a
437 better bookkeeping is needed.

438 7.1.1 Manual Certification

439 *Significant runs* are created and the corresponding quality flags are entered into the run registry
440 database by the central online DQM shifter who inspect DQM histograms and communicate
441 with the shift leader, DCS, DAQ and sub-detector shifters and experts. The runs entered in the
442 run registry is also checked by offline DQM shifters before individual subdetector experts check
443 the flags. Following the instructions provided by each sub-group, the shifter enters the quality
444 flags along with her/his observations and specific comments. Manual section of *Run-registry*
445 allows only one quality flag per sub-detector for each run unlike the case in the automatic
446 certification which is described in the next sub-section. The quality flags are entered in the run
447 registry database separately for online and multiple offline datasets including re-reconstructed
448 datasets.

449 Run-registry database also keeps a list of bad lumi sections for each partition of each sub-
450 detector using the DCS information obtained from scalers. This will be discussed in more
451 detail in the next section. As part of the certification procedure the *bad* lumi-section lists of
452 HCAL in run registry are also checked.

453 For certification of HCAL data, the summary values for online and offline datasets are also
454 checked. More thorough checks are made for the runs that have summary values below the
455 threshold values for each HCAL subdetector. When more detailed analyses are needed, the
456 observations are communicated to other HCAL performance group to investigate the problem.

457 To get more complete information for each run, the information provided by the HCAL shifter
458 is also checked. For this purpose, a web interface through the web-based monitoring tool,
459 WBM [11] is used to access the information that is logged into a database (*OMDS*) by the HCAL
460 shifter. The *comments* that are stored in the database by the shifter are particularly important
461 since they provide first hand information from the control room that could not have been ob-
462 tained automatically.

463 Combining all the certification information described above, the HCAL certification team de-
464 termines the goodness of each run taken during one week of data taking for each dataset and
465 checks the consistency of this decision with the HCAL quality flags in run-registry.

466 Using the manually run registry flags and the lumi-by-lumi flags in run registry, HCAL is found
467 to be 98.5% good in the run range 132440-136297.

468 7.1.2 Automatic Certification

469 Automatic certification is performed in the offline DQM including re-reconstructed data. Auto-
470 matic certification combines DQM, DCS, and DAQ summary values for each HCAL component

471 (HB,HE,HO0,HF) for each lumi section. HCAL DQM produces a simple count of bad channels
472 using the combined summary value at the end of each lumi section using dead cell lumi-by-
473 lumi, gidi, and raw data format histograms. The produced are normalized by the number of
474 events and number of channels at the end of each lumi section. Automatic certification is still
475 in development and it is planned to be completed in a few months.

476 7.1.3 Weekly Sign-off of Certification Results

477 The quality flags and additional checks and findings by the HCAL certification group are pre-
478 sented to the HCAL operations community every week to be able to commission the certifica-
479 tion procedure and to understand any remaining issues. Then, changes needed for run registry
480 quality flags and DCS lumi-by-lumi flags are communicated to the central DQM team. The
481 central DQM team collects certification information from each sub-detector, and then these are
482 *signed-off* in the weekly *Physics Validation Team (PVT)* meetings. After the sign-off of the quality
483 flags, a so-called 'JSON' file is produced for each dataset which lets analyzers to select only
484 *good* lumi-sections in their analyses. The quality flags are also stored in the offline condition
485 database and also the dataset bookkeeping system (DBS) [9].

486 8 Anomalous Signals in HCAL

487 Anomalous signals in HCAL have been observed while calorimeter modules were exposed to
488 test beams and during early commissioning with cosmic data [13]. Large reconstructed energies
489 were observed resulting from electronics noise as well as beam related effects. Figure 15 shows
490 the distribution of the number of channels within an RBX having energy above 1.5 GeV and
491 requiring that the total energy of the channels within the RBX is greater than 10 GeV. The events
492 were collected by triggering on energy deposits in the calorimeter and occur randomly. This
493 type of anomalous signal is collectively referred to as RBX/HPD noise. Several clear categories
494 of noise can be observed. Large signals are occasionally observed in the HCAL HPDs even
495 when no light is incident on the photo-cathodes. These signals are thought to originate by a
496 thermally emitted electron which ionizes the gas or surface molecule in the acceleration gap
497 of the HPD which in turn is accelerated back to the cathode liberating additional electrons.
498 Ion feedback typically affects 1 HPD channel. Dielectric flashover from the wall of the HPD
499 can produce large signals in up to 18 channels of the HPD. Electronics noise from the RBX can
500 produce large signals in up to 72 channels. the source of this type of noise is currently not
501 understood and is under investigation. Energy in the HB and HE is reconstructed from 4 time
502 samples of 24 ns and the chance of an overlap of the random RBX/HPD noise within this 100ns
503 window is small.

504 The rate of noise is continuously monitored and is seen to be relatively constant. Ion feedback
505 and HPD discharge appear relatively constant while RBX noise is seen to exhibit a greater
506 variation.

507 Anomalous signals were observed in the HF when modules were exposed to test beams. The
508 dominant source of the anomalous signals is due to a charged particle producing Cerenkov
509 light in the thick glass window of the HF PMT. A contribution is also observed from charged
510 particles traversing the fiber bundle behind HF.

511 The anomalous signals have distinct properties which can be exploited and filters developed
512 to remove the energy from these events. A summary of the filters that have been developed is
513 provided in the following sections. There are two approaches to filter noise. The energy recon-
514 structed in channels having anomalous signals can be removed during the event processing

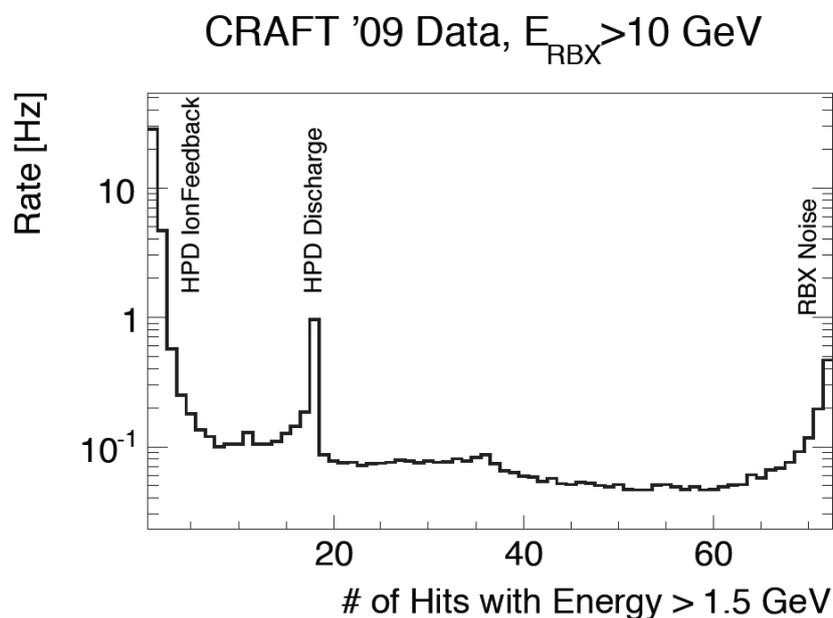

Figure 15: Number of channels within a RBX above threshold.

515 so that the flagged rechits do not contribute to the reconstructed physics objects. Since rechit
 516 filtering affects all users it is important to remove only well identified noise. As the event com-
 517 plexity increases it will become more difficult to use properties such as isolation to identify
 518 anomalous signals and more sophisticated filtering can be applied during the offline analysis
 519 level.

520 A flexible software framework was developed to provide the ability to remove rechits during
 521 data reconstruction, apply event filtering by the user, and to apply rechit cleaning by the user
 522 after the data has been processed. The energy for the calorimeter cells is reconstructed from
 523 the digitized data (digis) which is recorded in 10 time samples each having a 25 ns width. The
 524 digitized data is reconstructed as energy (rechit) and saved in the RECO (reconstructed) data
 525 format. The RecHit is a data structure containing energy, time, and flags which indicate the
 526 quality of the reconstructed quantities. Thresholds are applied to the rechit energies and the
 527 rechits are combined into a calorimeter tower structure having an electromagnetic and hadronic
 528 component. Physics objects such as jets and missing E_T are reconstructed started from the Calo-
 529 Tower. Filter can be applied to remove known sources of noise at the stage that the CaloTower
 530 is created producing what is referred to as “cleaned CaloTower”. One important limitation
 531 is that the full digi information is not available in the RECO data format. The implication is
 532 that filters that use digi information, such as the pulse shape, cannot be applied by the user on
 533 RECO data.

534 Additional filtering can be applied at the analysis level on top of the default filtering to cre-
 535 ate a custom cleaned CaloTower. This requires that any physics objects that are derived from
 536 CaloTower be recreated using the custom cleaned CaloTower. This flexibility allows users to
 537 develop and test filters which can then be applied by default during a subsequent reprocessing.
 538 It also allows users to take advantage of the most up to date cleaning without having to wait
 539 for the data to be reprocessed. Different analysis may require more aggressive cleaning which
 540 also can be applied at this stage.

541 The HCAL DPG has developed a set of baseline cleaning algorithms that are applied during
 542 the processing stage. Table ?? summarizes the algorithms and the details are provided in the
 543 following sections.

544 8.1 HF Noise

545 8.1.1 Introduction

546 Commissioning studies performed with data from the past test beams, cosmic runs, and early
 547 LHC beam runs have identified uncharacteristic noise (i.e. noise not produced solely from
 548 expected fluctuations in the electronics) in the forward hadronic calorimeter (HF) [13]. Such
 549 anomalous signals are caused by relativistic charged particles directly impinging upon the
 550 window of an HF photomultiplier tube (PMT), generating Cerenkov light, and thereby pro-
 551 ducing an abnormally large apparent energy signal for the single HF channel associated with
 552 that PMT. Due to the nature of the signal generation, the energy spectrum of such noise is rel-
 553 atively well defined, with a peak at an energy of $E \approx 100$ GeV and pronounced tails at higher
 554 energy values. Since the HF detector occupies the forward region of CMS, the bulk of the trans-
 555 verse energy (E_T) spectrum of such noise is mostly constrained to relatively low values, e.g.,
 556 an energy of 100 GeV corresponds to $E_T = E / \cosh(\eta)$ of ≈ 10 (1.3) GeV at $\eta = 3$ (5). Never-
 557 theless, such anomalous signals can occasionally produce fake jets with high p_T and large fake
 558 in the event. The application of the HF noise cleaning algorithms, described in this section, is
 559 therefore recommended for any physics analysis which employs energy deposits reconstructed
 560 in HF and/or . A fully comprehensive description on the HF noise cleaning algorithms and the
 561 complete set of results on their performance can be found at [ADD HERE NOTE NUMBER OF
 562 HF DETECTOR NOTE].

563 8.1.2 Handles to identify anomalous signals

PMT hits are typically characterized by a large apparent energy in a long (short) fiber and
 very little or no energy in the short (long) fiber in the same HF tower; in addition they are
 usually more “isolated” than real energy deposits, i.e. very little or no energy is observed
 in the surrounding HF towers. The topology of PMT window hits can be compared against
 expected longitudinal and lateral shower profiles in HF. PMT hits are typically characterized
 by a large apparent energy in a short fiber and very little or no energy in the long fiber in the
 same HF tower, as shown in Figure 16. Therefore, a simple ratio

$$R = \frac{E_L - E_S}{E_L + E_S}, \quad (2)$$

564 where E_L and E_S are the respective energies of the long and short fiber RecHits in a given HF
 565 tower, can be used to identify the short fiber PMT hits. The PMT hits in short fibers will have
 566 $R \approx -1$.

567 The pulse shape of the PMT hits, originated by the Cerenkov light produced in the PMT win-
 568 dow, is expected to be almost fully contained within a single 25-ns time window, as are the
 569 pulses of signals generated by particles showering in the HF absorber. However, the PMT hit
 570 signal is expected to arrive earlier in time (by several ns) with respect to the signal from real
 571 energy deposits. This is due to the fact that Cerenkov light produced in the HF fibers by par-
 572 ticle showers requires additional time to reach the PMTs (quartz fibers have a high index of
 573 refraction, $n = 1.458$, and varying length that increases with increasing η).

574 Figure 17 is a scatter plot of the ratio R , defined as $R = (E_L - E_S) / (E_L + E_S)$, vs the recon-
 575 structed time of both long and short fibers with energy E_L and E_S , respectively, above 90 GeV,

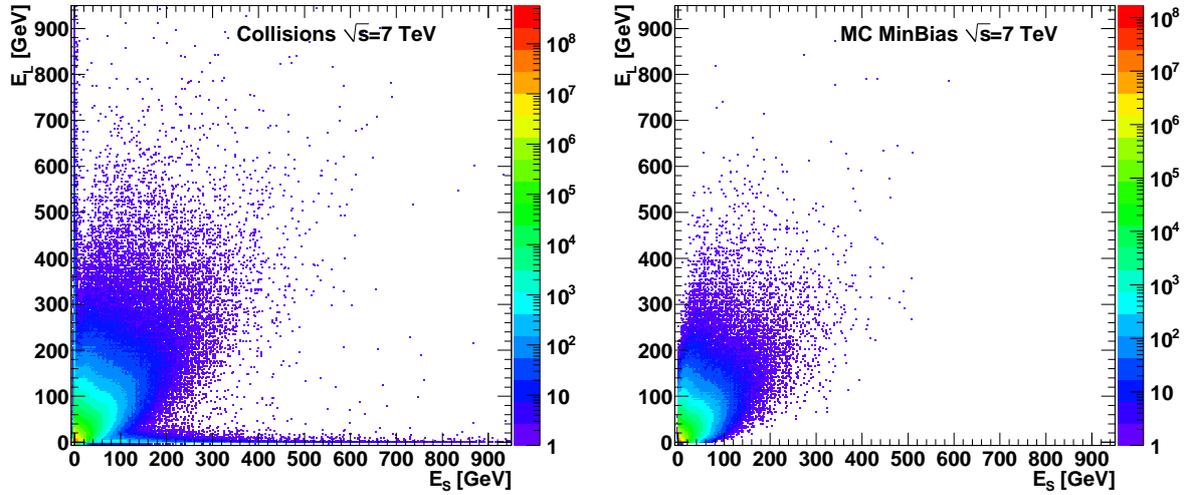

Figure 16: Long fiber RecHit energy vs. short fiber RecHit energy from the same HF tower in 7 TeV collision data (left) and 7 TeV MinBias Monte Carlo simulation (right). High energy entries close to either of the two axes only present in collision data (left plot) are the HF PMT window hits.

576 from a sample of 7 TeV collision data. High energy deposits that have R value close to -1 or
 577 1 (corresponding to energy present only in short or long fibers, respectively) and/or that are
 578 early in time (approximately $t < -10$ ns), can be potentially flagged as PMT hits. Figure 17
 579 indicates that also late hits (approximately $t > 10$ ns) are present in collision data. The exact
 580 source of late hits is not yet fully understood. However it can be noted that most of late hits
 581 have also topological properties consistent with some type of anomalous signal (R close to -1
 or 1).

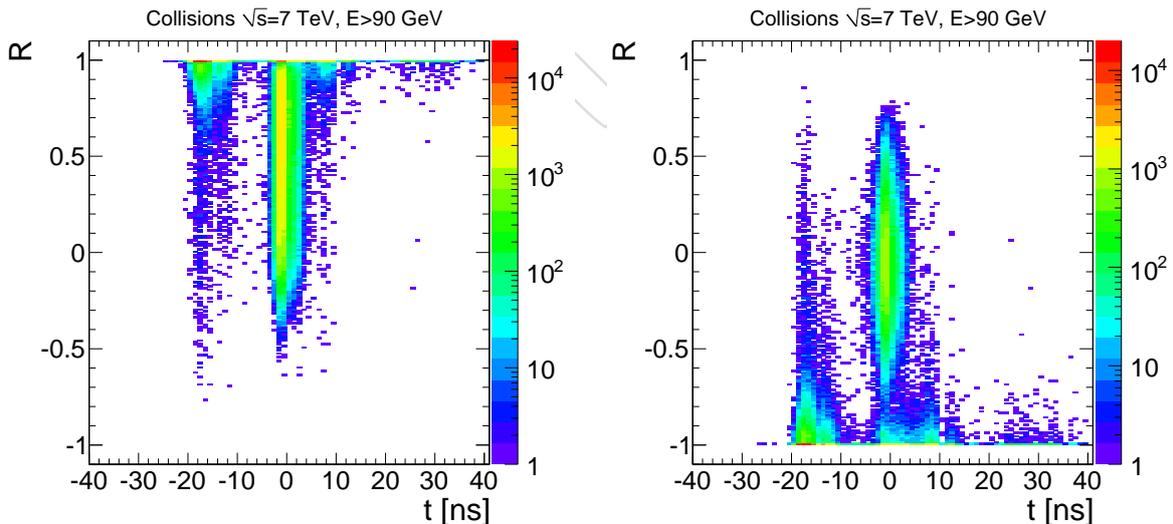

Figure 17: R ratio vs. reconstructed time for long (left) and short (right) fiber reconstructed hits with $E > 90$ GeV in 7 TeV collision data.

8.1.3 Description of HF noise cleaning algorithms

Based on these considerations, the main handles to identify the HF PMT window hits (and anomalous HF signals in general) are the topology of their energy depositions in η/ϕ /depth space and the pulse shape/timing of the signals.

The topology of PMT window hits can be compared to the expected longitudinal and lateral shower profiles in HF. Two different algorithms are used for short and long fibers, respectively:

- the Polynomial Energy Threshold (PET) algorithm flags a reconstructed hit in a short fiber as a PMT hit if its energy, E_S , is i) above some energy threshold, and ii) very large compared to the long fiber energy, E_L , in the same HF tower. The energy threshold is a polynomial function of η , ranging from about 35 GeV (at $\eta = 3$) to 50 GeV (at $\eta = 5$). If this threshold is passed, and the ratio $R = (E_L - E_S)/(E_L + E_S) < 0.8$, the cell is identified as a PMT hit;
- the S9S1 algorithm, employed for long fibers, allows to identify the PMT hits by comparing the energy in a long fiber to the sum of energy in 9 of its neighbors (4 long fibers and 4 short fibers in the adjacent HF towers, plus the short fiber of the same HF tower). The isolation variable "S9S1" is defined as a ratio between the energy sum of the 9 neighbors, S9, and the energy of the long fiber cell under consideration, S1. If this ratio is smaller than a threshold, defined as a function of long fiber energy, the cell is flagged as a PMT hit.

The S9S1 algorithm is found to be less efficient at identifying PMT hits (mostly at $E_T < 10$ GeV) with respect to PET algorithm. The use of the S9S1 algorithm is motivated by the need of making the noise cleaning in long fibers safe for real energy deposits coming from isolated photons and electrons. In fact, high energy photons and electrons hitting HF can occasionally deposit large fraction of their energy in the long fibers and very little energy in short fibers at a given (η, ϕ) location, thus faking the PET signature of an isolated PMT hit. While PET algorithm can incorrectly flag such events, the S9S1 algorithm is safe since it takes into account that electrons and photons will deposit some energy in the adjacent cells as well. The HF ring at the smallest η ($i\eta = 29$, i.e. $\eta = 3$) represents an exception, since it's partially shielded by the HE material, and it receives very little energy coming from the interaction point. For this reason, the PET algorithm can be safely used to identify PMT hits occurring in the $i\eta = 29$ ring.

In addition to the topological cuts, the pulse shape/timing information of the signals are used to identify PMT hits in both long and short fibers. In order to employ the expected timing difference between regular signals and PMT hits, a precise phase alignment in HF is required. A phase scan in HF was performed in April 2010 with early 7 TeV collision data and the timing phase was adjusted in the hardware settings so that the PMT hits show up in an earlier time sample than the normal energy deposits. More details on the HF phase scan are discussed in Section 4.2.

As a result of the timing adjustment, real signals are expected to peak in time slice 4 for all channels in HF. The fast response time of the PMTs means that the bulk of the charge for real HF signal pulses will be recorded in this single time slice. PMT window hits differ from real signals in that they generally arrive earlier or later than real signals. Even window hits arriving within the expected signal time range typically have broader distributions than real signals. The shape of the HF pulse can thus be used to distinguish real signals from PMT window hits. For each HF hit reporting an energy of at least 40 GeV, the charge deposited in time slice 4 (TS_4) is compared to the total charge in the larger time range between time slices 3 and 6 ($\sum TS_3 - 6$).

An HF hit is flagged as noise if the following condition is met:

$$\frac{TS4}{\sum TS3 - 6} \leq 0.93 - \exp(-0.38275 - 0.012667 * E), \quad (3)$$

620 where E is the energy of the hit. This cut flags both early and late hits, as well as in-time hits
621 that report significant charge outside the expected signal time range.

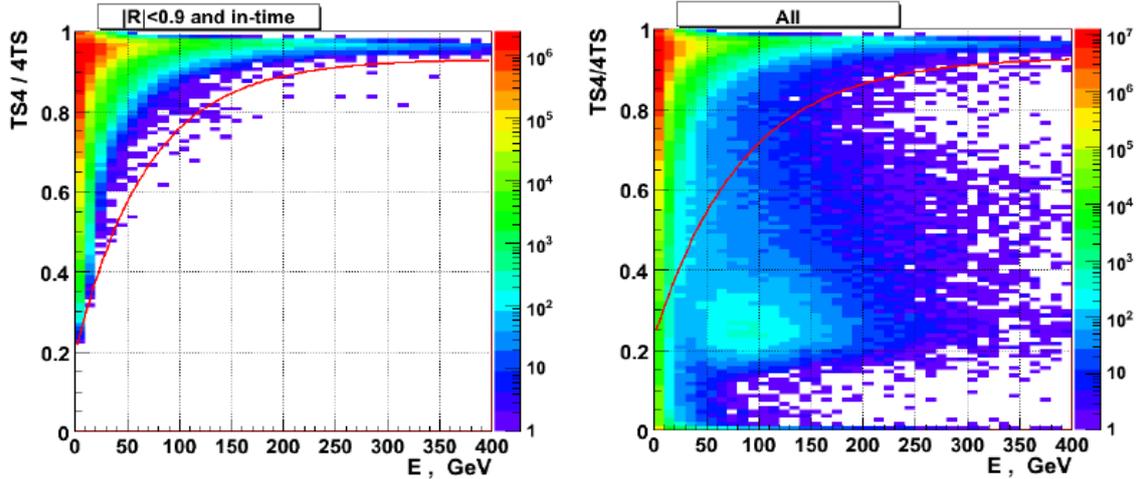

Figure 18: Q ratio (“ $TS4/4TS$ ”) vs Energy for (left) in-time RecHits with $|R| < 0.9$ and (right) all RecHits. The line indicates the contour used to separate good energy deposits from anomalous signals.

622 Figure 19 shows the reconstructed time for all energy deposits in long and short fibers above
623 40 GeV, and for those flagged by topological and pulse shape cleaning algorithms, in 7 TeV
624 collision data. It should be noted that i) the use of pulse shape cleaning improves significantly
625 the efficiency in identifying PMT hits occurring in long fibers, ii) some energy deposits in long
626 and short fibers are flagged by the topological cuts but they are reconstructed in-time and not
627 flagged by the pulse shape algorithm. Therefore, the combination of pulse shape and topolog-
628 ical cleaning provides a set of complementary criteria to identify anomalous signals in HF.

629 HF channels flagged by either the topological cuts (PET, S9S1) or the pulse shape algorithm are
630 removed from the reconstruction of high level objects, such as jets and . It is relevant to point
631 out that i) the reconstructed time/pulse shape for HF energy deposits from collision data is not
632 optimally reproduced by the current simulation, ii) the HF anomalous signals are not included
633 in the current simulation. For these reasons, the pulse shape cleaning algorithm is currently
634 applied only to collision data. The topological cleaning is instead applied to both data and
635 simulation.

636 8.1.4 Performance of HF noise cleaning algorithms

637 The topological cleaning (PET, S9S1) was applied to Monte Carlo samples of different physics
638 processes (Minimum Bias, QCD multi-jets in different ranges of jet p_T , isolated photons in the
639 HF acceptance in different p_T ranges) to evaluate the efficiency of the flagging algorithms on
640 the simulated energy reconstructed in individual HF channels, as well as the impact on jets
641 reconstructed in HF and MET. The probability to incorrectly flag a real energy deposit in HF
642 with $E_T > 5$ GeV as an anomalous hit, is estimated to be less than 10^{-3} for the physics processes
643 considered; this value is considered small enough to allow the application of this cleaning by
644 default in the standard CMS reconstruction.

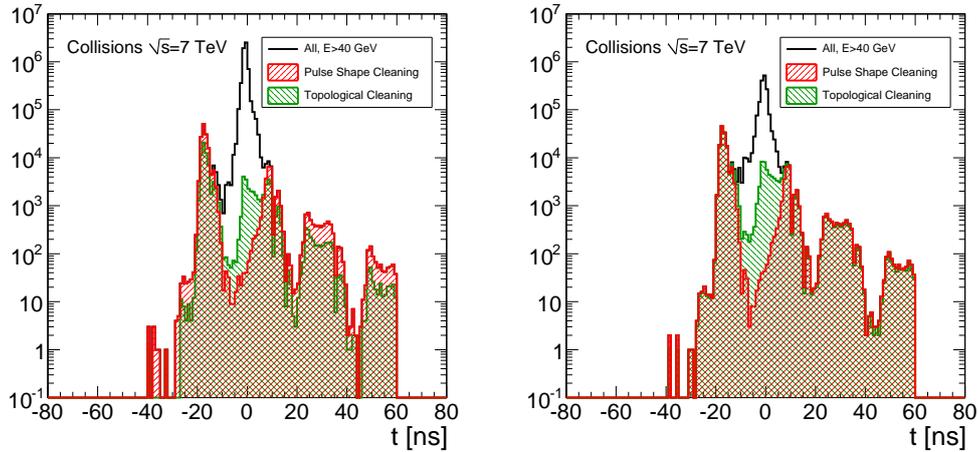

Figure 19: TO BE UPDATED WITH NEW PLOTS. Reconstructed time for energy deposits above 40 GeV in long (left) and short (right) HF fibers in 7 TeV collision data. Reconstructed hits flagged by topological and pulse shape cleaning algorithms are also shown.

645 The performance of the topological and pulse shape cleaning algorithms has been studied on
 646 a sample of 7 TeV pp collision data triggered by minimum bias triggers and jet/met triggers.
 647 An offline event selection to identify good collision candidates is applied, including the re-
 648 quirement of i) two proton bunches crossing in the center of CMS, ii) a good reconstructed
 649 primary vertex, and iii) the removal of data collected during periods with known detector
 650 problems. Beam related background events (including beam halo and beam scraping events)
 651 are removed by appropriate filters that use trigger and tracker information, respectively. Events
 652 with HPD/RBX noise in HCAL barrel and endcaps are removed from the analysis as described
 653 in Section 8.2. Finally, anomalous noisy channels observed in the ECAL barrel (so called “ECAL
 654 spikes”) are flagged and removed from the jet and MET reconstruction using the recipe pro-
 655 vided by the ECAL group.

656 Figure 20 shows the calorimeter-based MET before and after applying the topological and pulse
 657 shape cleaning algorithms in HF. It is observed that the noise cleaning algorithms strongly
 658 reduces the tails in MET distribution caused by HF anomalous noise. Figure 21 shows the
 659 cleaned calorimeter-based MET in data compared with a Monte Carlo simulation of Minimum
 660 Bias events; the good agreement between data and simulation confirms that the cleaning al-
 661 gorithms remove efficiently the HF noise, without affecting the real energy deposits from col-
 662 lisions. Some events due to residual HF noise are still visible in the tails of the MET. They
 663 have been visually inspected and classified as i) double-hits in the same HF tower, ii) multi-
 664 hits affecting several channels typically in the same ϕ strip, and iii) PMT hits embedded inside
 665 a jet. Such residual anomalous hits, not flagged by the existing algorithms and producing
 666 high MET ($\text{MET} > 45 \text{ GeV}$), occur at a very small rate of approximately 10^{-4} with respect to the
 667 total rate of identified anomalous hits in HF. Nevertheless, new criteria to identify this kind of
 668 noise are currently under study and will be presented in future updates of this analysis.

669 This section concludes with a couple of remarks on the characteristics of the PMT hits. One
 670 of the properties noticed in collision data is that the rate of HF PMT hits per event roughly
 671 scales linearly with the amount of energy deposited in HF, excluding the energy of the PMT
 672 hits themselves. This is shown in the left plot of Figure 22 for 7 TeV collision data, where
 673 PMT hits were identified using both topological and pulse shape algorithms. Based on this
 674 linear dependence and the mean $\sum E$ in HF coming from Monte Carlo simulation of any type
 675 of process, one can roughly predict the rate of PMT hits in such events. It can also be noticed

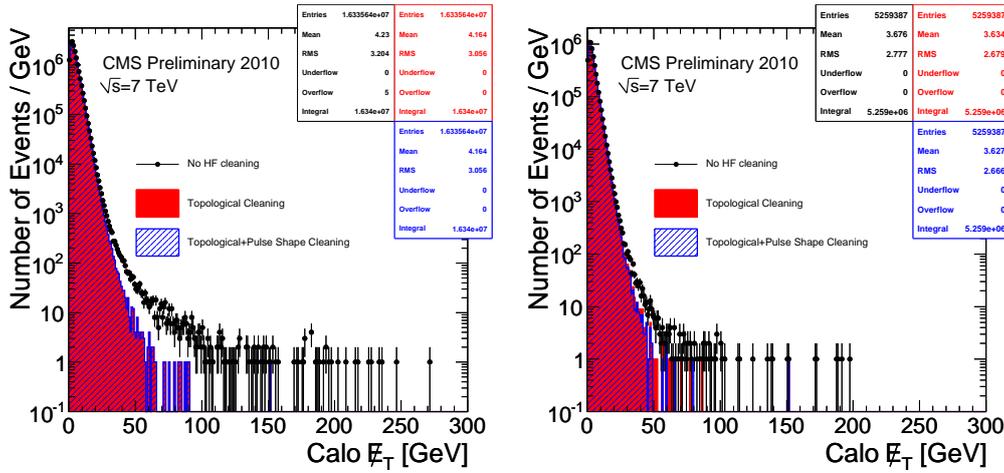

Figure 20: TO BE UPDATED WITH NEW PLOTS. Calorimeter-based MET in $\sqrt{s} = 7$ TeV pp collision data before and after applying topological and pulse shape cleaning in HF. The offline selection for good collision events, described in the text, as well as the ECAL barrel noise cleaning and the event filter for HPD/RBX noise are applied. The plot on the left represents the whole statistics of the data-sample analyzed; the right plot includes only events passing the minimum bias triggers. The number of events in the right plot is smaller than the left plot because the minimum bias triggers were prescaled.

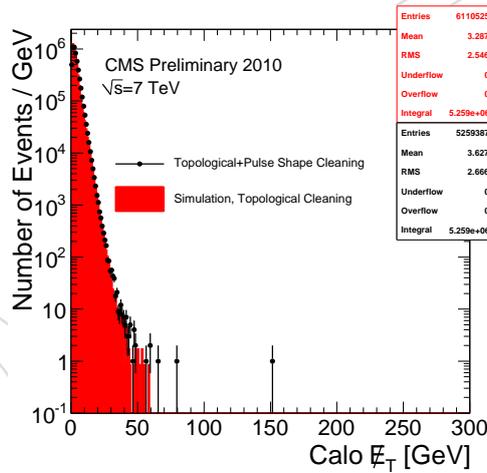

Figure 21: TO BE UPDATED WITH NEW PLOTS. Calorimeter-based MET in $\sqrt{s} = 7$ TeV pp collision data after applying topological and pulse shape cleaning in HF, compared with a Monte Carlo simulation of Minimum Bias events. The offline selection for good collision events, described in the text, as well as the ECAL barrel noise cleaning and the event filter for HPD/RBX noise are applied. Only events passing minimum bias triggers are considered for the comparison.

676 that, despite of the fact that HF PMT hits most frequently occur as single hits, cases of multiple
 677 hits in a single event have also been identified, as shown in the right plot of Figure 22.

678 8.2 RBX/HPD Noise Event Filter

679 Event displays showing RBX and single HPD noise are shown in Figure 23. There are 18 channels in aHPD and within a subdetector (HB or HE) towers having the same *phi* are read out
 680 by a single HPD. Four HPDs are connected to one readout box (RBX) through 4 readout modules
 681

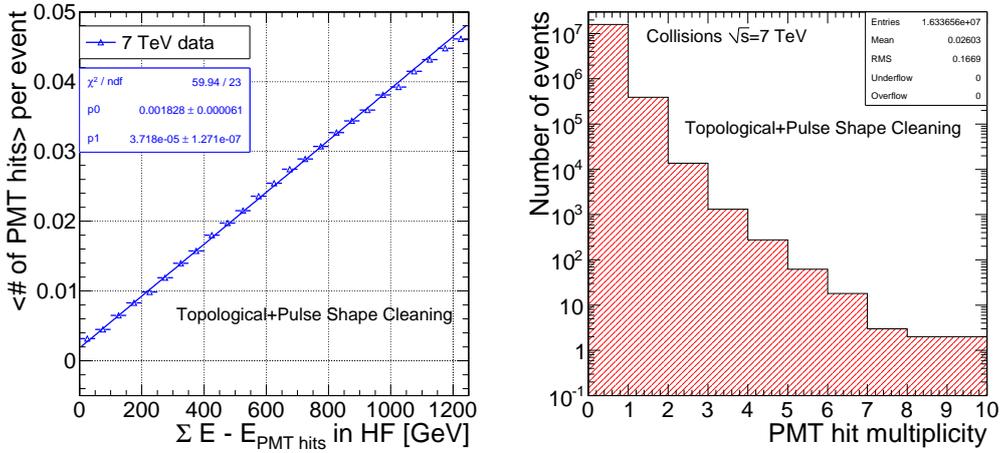

Figure 22: TO BE UPDATED WITH NEW PLOTS. Left plot: Average number of HF PMT hits per event as a function of $\sum E$ in HF, excluding the energy of the PMT hits, in 7 TeV collision data where PMT hits were identified using both topological and pulse shape algorithms. Right plot: HF PMT hit multiplicity in 7 TeV collision data obtained using both topological and pulse shape algorithms.

(RM).

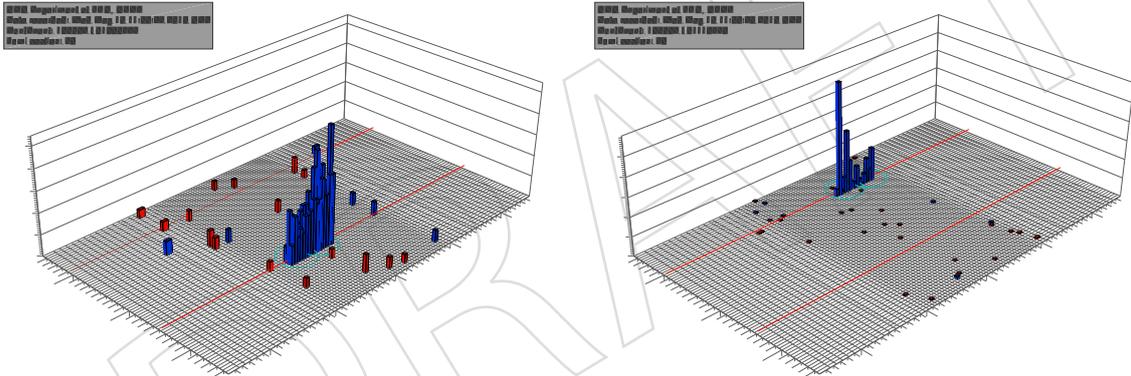

Figure 23: Characteristic pattern of energy deposited due to RBX noise (left) and HPD discharge (right). RBX noise can affect up to 72 channels of 4 HPDs being readout by the same Readout Box. HPD noise can effect up to 18 channels.

682

683 Some properties of RBX/HPD noise which can be used to identify noise includes the following.

684

- Large signals are observed for channels associated with either the RBX or HPD. This produces a distinct pattern of energy in eta, phi which is isolated and does not have any significant surrounding energy. The noise is random and the overlap with a collision is rare ($\sim 10^{-5}$). Typically there is little or no other activity from the other detector components.

688

689

- Since the noise is random, it is not in time with a physics collision. The rechit time or the pulse shape will be an effective handle to suppress the noise.

690

691

- We observe a low rate of events that have an ADC=0. This is a characteristic of so called "Flash" noise where a large pulse will undershoot the pedestal resulting in

692

693 ADC=0.

694 Since the overlap of RBX and HPD noise with a collision event is rare it is possible to reject
 695 events identified as having RBX/HPD noise. The RBX/HPD noise event filter discussed here
 696 is recommended by the CMS HCAL Detector Performance Group for the summer 2010 analyses
 697 of pp collision data delivered by the LHC with 25 ns bunch crossing and at $\sqrt{s} = 7$ TeV.

698 The event filter removes events based on the following variables and requirements:

699 • **HPD Hit Multiplicity:** Events are identified as noise if there are more than 17 channels
 700 in an HPD having $E > 1.5$ GeV. Different settings for the threshold values (0.5-10 GeV) and
 701 number of HPD hits (14-18) were tried and the chosen settings were found to provide good
 702 noise rejection while maintaining a high signal efficiency.

703 • **Hot HPD:** The event is flagged as noise if a single HPD has $N_{HPD}^{hits} \geq 10$ with $E > 1.5$ GeV
 704 and there are no hits in the other HPDs within the same RBX (independent of the RBX energy).
 705 HPDs that satisfying the second condition are referred to as a “hot HPD”. If there is at least one
 706 hot HPD in the event the event should be removed.

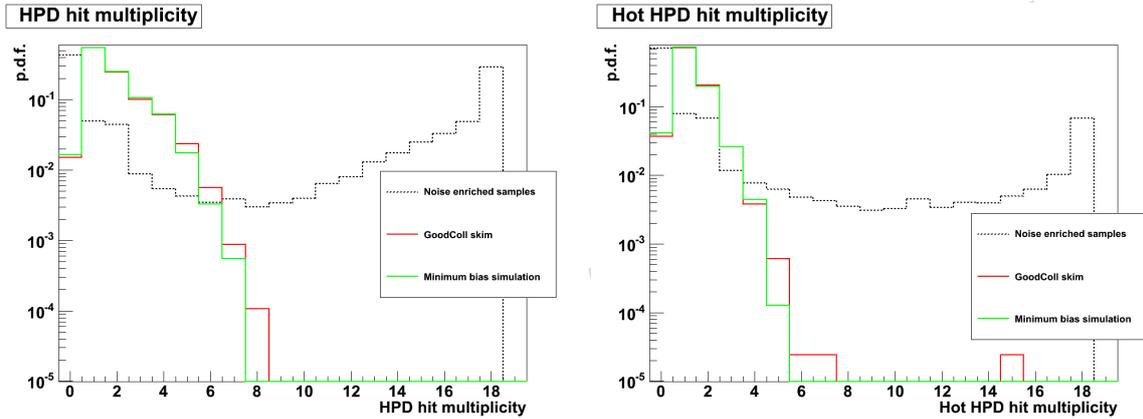

Figure 24: HPD Hit Multiplicity and Hot HPD hit multiplicity in all the CMS collected and Monte Carlo Simulated samples studied

707 Figure 24 shows the N_{HPD}^{hits} , N_{hotHPD}^{hits} for the default filter threshold and the after the baseline
 708 selection has been applied.

709 • **E2/E10:** The ratio E2/E10 is constructed for all channels associated with the RBX that have
 710 $E > 1.5$ GeV. E2 is the maximum of the sum of two consecutive time samples within the 10 TS
 711 used to digitize the data. E10 is the sum of the charge for all ten TS for all channels associated
 712 with the RBX that pass the requirement of $E > 1.5$ GeV. The E2/E10 distribution for $E_{RBX} > 50$
 713 GeV in the samples studied after the baseline selection is shown in Figure 25.

714 The event filter discards events as “RBX noise” if $E2/E10 > 0.96$ or $E2/E10 < 0.7$ and $E_{RBX} >$
 715 50 GeV. We observe that the MC simulation does not reproduce the pulse shape of the data and
 716 work is ongoing to improve the simulation.

717 • **ADC0:** One class of RBX/HPD noise that is observed is referred to as “RBX Flash Noise”.
 718 Large pulses are observed that will undershoot the pedestal resulting in ADCs having 0 counts.
 719 A subset of these events are identified by the “HPD Hit Multiplicity” requirement, however
 720 there are events with lower channel energy that survive. The remaining noise events can be fil-
 721 tered using the a cut on the number of channels within a RBX observed to have ADC=0 (ADC0)
 722 This type of noise is not modeled in the Monte Carlo Simulation. The $N_{ADCZero}$ distribution af-

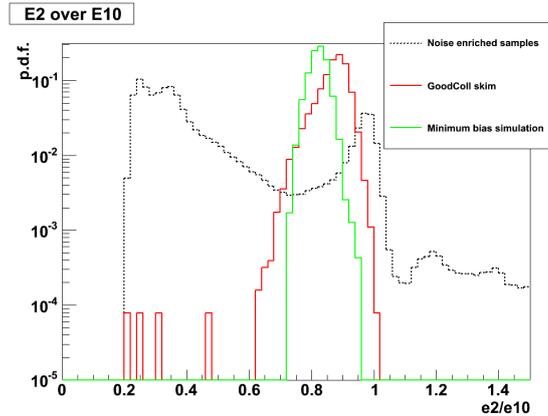

Figure 25: $E2/E10$ (for $E_{RBX} > 50$ GeV) for the noise enriched data, good collision data, and several different MC samples.

723 ter the baseline selection is shown in Figure 27.

Figure 26: Pulse shape for channel with $ADC=0$.

724 Events are removed if $N_{ADCZero} > 10$ in an RBX with $E > 10$ GeV.

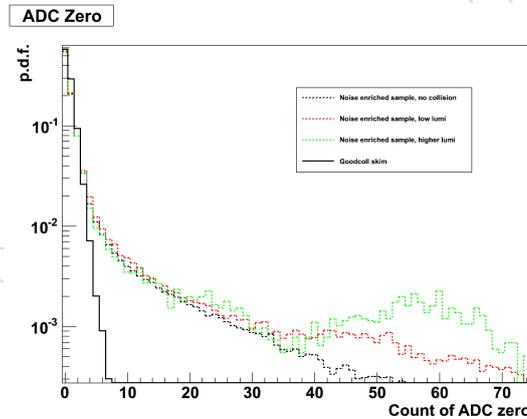

Figure 27: $N_{ADCZero}$ in all the CMS collected data samples

725 Events are dropped as noisy if $N_{ADCZero} > 10$ in an RBX with $E > 10$ GeV.

726 Figure 28 shows the rehit time distribution for the high MET sample, and a pure noise sample.
 727 The RBX/HPD noise is seen to be distributed across the entire 4 TS window as expected since it
 728 occurs randomly while the time of energy from collisions is grouped near 0. Sufficient collision
 729 data is needed to adjust the channel phase and a good understanding of the pulse shape is
 730 needed. Once this work is done we expect to have more sophisticated algorithms that use time
 731 or use the χ^2 from the fit to the pulse shape in order to identify anomalous signals.

732 8.3 Performance of the RBX/HPD Noise Event Filter

733 In Table ?? we show the rejection efficiency of each of the requirements of the filter normal-
 734 ized to the baseline selection (i.e. $L1SingleJet10$ trigger and at least one RBX with $E_{RBX} > 50$

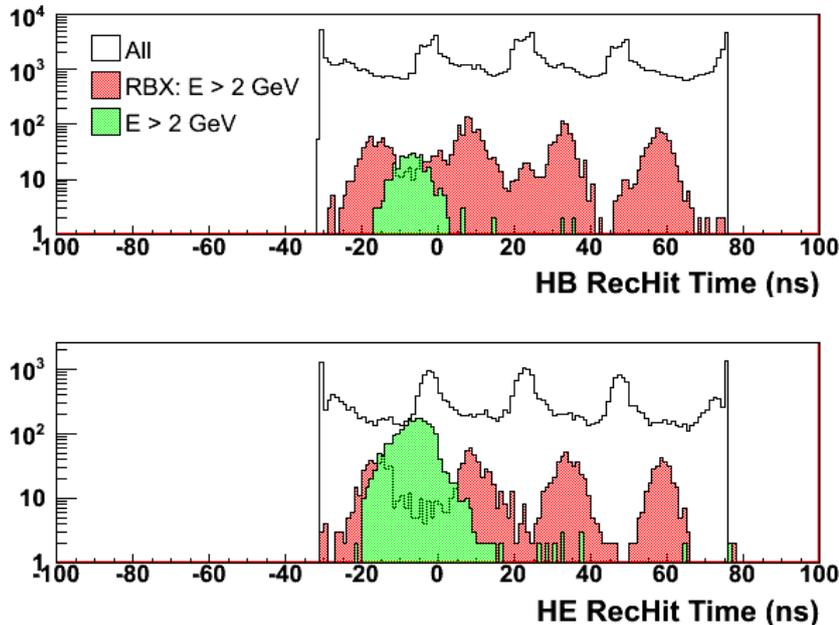

Figure 28: The rechit time for events that remain in the high MET tail ($\text{MET} > 45 \text{ GeV}$) compared with a pure noise sample. The RBX/HPD noise is random and occurs uniformly over the entire 4 TS window, while energy deposits from collision data is grouped near 0.

735 GeV). In the “pure” noise runs (absent beam) the maximum variation is on the HPD hit mul-
 736 tiplicity requirement while the application of the entire filter has the same rejection efficiency
 737 within a couple of percent. The results from the collision data runs and the same baseline (i.e
 738 L1SingleJet10U_noBPTX trigger and at least one RBX with $E_{RBX} > 50 \text{ GeV}$) are also compatible
 739 overall with the pure noise runs results. For the collision data (gated with the BPTX) 1% of the
 740 events are rejected almost exclusively from the E2/E10 requirement of the filter (always nor-
 741 malized to the baseline). Additional studies need to be performed to determine if these events
 742 are misidentified events as noise and/or noise events from other sources. The corresponding
 743 events rejected in the Minimum Bias MC sample are 0.1% from the same requirement. Finally
 744 less than 0.5% of signal top MC events (with and without pileup) and SUSY events are rejected
 745 also single handily from the E2/E10(RBX(50)) requirement of the filter.

746 We have also studied the filter using only the L1SingleJet10U as baseline and the relative
 747 rejection rates are understood.

748 8.4 HCAL Noise Filters at the HLT

749 Anomalous HB/HE noise with energy $> 20 \text{ GeV}$ occurs at a rate as high as 20 Hz, as mea-
 750 sured in 2009 CRAFT data, although the exact rate has dependencies on detector conditions
 751 which change with time. This rate comprises a substantial fraction of the total HLT bandwidth.
 752 Table 1 shows the expected trigger rate due to physics events and due to HB/HE noise for
 753 common jet and missing E_T HLT paths. The menu assumes an instantaneous luminosity of
 754 $8 \times 10^{29} \text{ cm}^{-2} \text{ s}^{-1}$, the noise rate is extrapolated from 2009 CRAFT data, and the physics rate is
 755 extrapolated from lower instantaneous luminosity collision runs from May 2010.

756 Although the total rate of HB/HE noise is high compared to the HLT bandwidth, it is still
 757 quite low with respect to the crossing rate (40 MHz). As the presence of this type of noise

8E29 Menu ($\sqrt{s} = 7$ TeV)

Path Name	Total Prescale	Physics Rate (Hz)	HB/HE Noise Rate (Hz)	Noise Rate After Filtering (Hz)
HLT_Jet15U	20	5.7 ± 1.2	~ 0.6	~ 0.3
HLT_Jet30U	1	11.5 ± 1.7	~ 7.7	~ 2.5
HLT_Jet50U	1	1.7 ± 0.6	~ 5.0	~ 0.9
HLT_MET45	1	~ 0.5	~ 6.4	~ 1.2
HLT_MET100	1	~ 0.0	~ 2.2	~ 0.3

Table 1: Expected rate for events triggered by physics and events triggered by HB/HE noise in different jet and missing E_T HLT paths in the 8E29 menu for pp collisions at $\sqrt{s} = 7$ TeV. Note that the rate is dominated by noise in the HLT_Jet50U, HLT_MET45, and HLT_MET100 paths. The last column of the table presents the expected HB/HE noise rate after the filtering procedure described in this section.

$E > 50$ GeV RBX with:

$E2/E10$ outside the range $[0.65, 0.98]$, or
 ≥ 10 ADC 0 counts, or
contains an HPD with ≥ 17 hits, or
contains an HPD with ≥ 10 hits and no other hits in the RBX

and the RBX has an EMF $< 2\%$
and ≤ 2 RBXs with $E > 10$ GeV in the event

Table 2: Summary of conditions for rejecting an event as HB/HE noise at the HLT. The $E > 50$ GeV RBX must be noisy, have a low electromagnetic fraction, and be only one of two energetic RBXs in the event. These requirements have a high efficiency for identifying noisy events, while maintain a very low misidentification rate.

758 is predominantly a stochastic process, the probability of noise overlap with a collision that
759 would otherwise have fired the trigger is very low (measured to be at most a part in 10^5).
760 Therefore, in the initial phases of CMS detector commissioning when LHC buckets are mostly
761 empty, requiring that a trigger is coincident with the presence of beam substantially reduces
762 the impact of anomalous noise at the HLT. As LHC buckets continue to be filled, this condition
763 will be degraded and beam coincidence will no longer be sufficient to suppress HB/HE noise.
764 A different approach will be necessary.

765 We can use the same techniques to reject noise described in previous sections to reject events
766 that contain noise at the HLT. Because rejected events at the HLT are unrecoverable, we modify
767 the conditions of the algorithm to suppress the rate of noise misidentification to levels better
768 than one part per 10^4 . Much like before, we look for high energy RBXs which present the
769 characteristics of anomalous noise, but we also require that the RBX has an electromagnetic
770 fraction less than 2%. This requirement ensures that the RBX is unlikely to be due to a high
771 energy jet that has a pulse shape that fluctuates in a uncharacteristic manner. Moreover, we
772 require that there are at most two RBXs with $E > 10$ GeV. Since noise events will typically
773 overlap with minimum bias collisions or no collision at all, this requirement minimizes the
774 likelihood that noise is coincident with anything but soft collisions. Table 2 summarizes the
775 requirements for event rejection at the HLT.

776 By applying these requirements as a filter to events that pass the jet and missing E_T paths
777 at the HLT, we find a very high efficiency for noise identification. The expected rates from

2009 CRAFT data after filtering are shown in the last column of Table 1. The overall rate of HLT triggers due to HB/HE noise is reduced approximately 65%. The same filter can be applied to events in MC to test the misidentification rate. We find that out of 5,000 simulated $t\bar{t}$ events, none were identified as noise by this filter. Preliminary tests of the misidentification rate from events collected directly by the HLT suggest a similarly low rate. While studies of this procedure are ongoing, we believe that this process will be crucial to mitigating the effects of anomalous HB/HE noise at the HLT.

8.5 Simulation of HCAL Noise

Figure 29 shows a GEANT4 simulation of the production points of particles hitting PMT glass windows in 7TeV minimum bias collisions. Fifty nine percent of those are muons (black dots) from decay in flight of pions and kaons before HF along the path from primary vertex toward PMTs. Thirty five percent are electrons (blue) produced in material just before PMTs. Most of those electrons are traced to leakage of hadronic showers in HF. Six percent are pions (red) and kaons (green) from hadron showers in HF.

Figure 30 shows the number of the HF PMT hits as a function of energy in HF in 7TeV collision data. PMT hits were identified using the algorithm described below and were removed from the energy calculation. The number of anomalous increases linearly with the HF energy. GEANT4 simulation reproduces the trend, but shows some deficiency. Tuning of GEANT4 simulation is in progress.

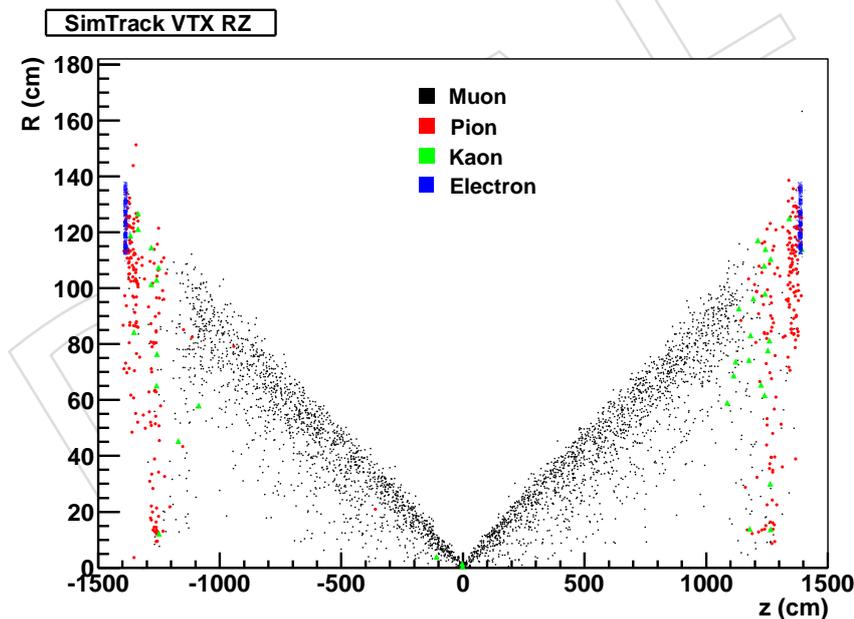

Figure 29:

9 Operating Experience

10 Summary and Outlook

The HCAL is an essential component of the CMS detector. Searches for new physics using a missing E_T signature will rely heavily on a good understanding of the HCAL performance.

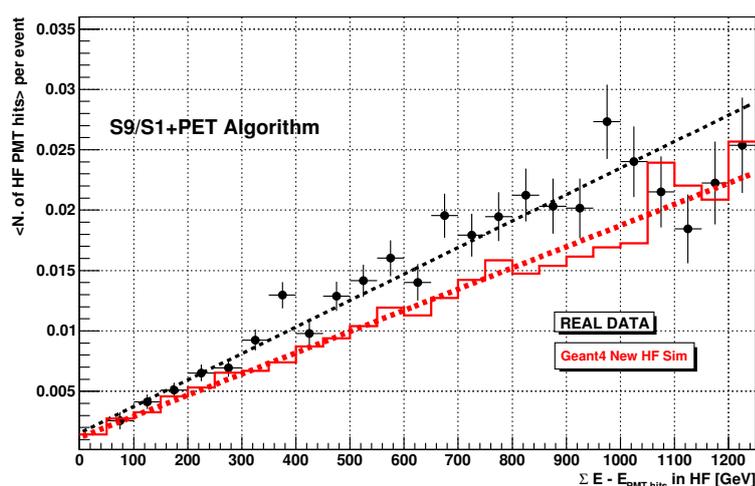

Figure 30:

801 The CMS HCAL has been precalibrated in the test beam in order to reproduce the response of
 802 50 GeV pions. Additional tuning has been performed using cosmic and beam splash events in
 803 order to smooth out any channel by channel variation. This precalibration condition does not
 804 take into account additional material of CMS once it is fully assembled. A strategy to determine
 805 the HCAL response using collision data has been developed. The in situ calibration requires
 806 non zero suppressed data in order to apply relative corrections in phi. Isolated charged particles
 807 are then used to set the energy scale and determine the response as a function of eta. Special
 808 triggers have been defined in order to collect sufficient samples of events for the calibration.
 809 The calibration procedure is being tested using low momenta tracks and we have observed
 810 some discrepancies in the MC response. As we collect more data we will be able to examine
 811 the Data/MC agreement over a wide range of variables.

812 The development of extensive monitoring tools allows for the early detection of problems help-
 813 ing to ensure we collect good data with a high efficiency. HCAL monitoring shifts and a prompt

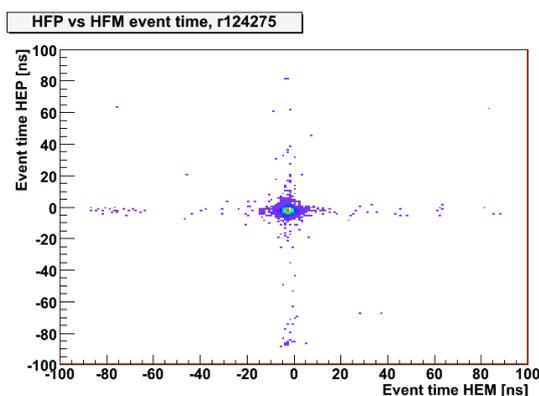

Figure 31: The HF time.

814 feedback team are available to quickly respond to problems and assist in tracking down the un-
815 derlying source. Special procedures have been developed to respond to hardware faults. For
816 example a hot trigger tower resulting in a high trigger rate can easily be masked. The detector
817 conditions are continually monitored and any necessary changes to the reconstruction condi-
818 tions can be updated during offline processing. In some cases a team of experts are assembled
819 in a Working Group to study problems and develop solutions. This arrangement has been
820 working well but it does rely extensively on a few key people. It will be necessary to devel-
821 oped a deeper pool of experts to provide continuous coverage for the life of the experiment.
822 The monitoring tools have to be efficient at detecting causes of problems so that quick action
823 can be taken. we expect that the monitoring tools will require continuous development and
824 adaption to detect new problems.

825 The data is certified as “good for physics” by a special team. Results from online and offline
826 Data Quality Monitoring are used as the primary input to the decision. Additional information
827 is collected from entries by the shift crew using the “shifter checklist”, Logs, and a list of known
828 problems. This collection of information is time consuming and work is ongoing to automate
829 the collection of the information and to present it in an easy to interpret format. Ultimately the
830 procedure should be fully automated.

831 Several sources of anomalous signals are identified and algorithms to remove the associated
832 energy have been implemented. The main sources of anomalous events in HCAL come from
833 HF PMT window interactions associated with collisions and a low rate of random RBX/HPD
834 noise. The HF is a Cerenkov calorimeter with a very fast response allowing the possibility to
835 separate early arriving particles impacting the PMT window from the light signals generated in
836 the bulk of HF. Collision data was used to adjust the phase of the HF so that energy deposits
837 from collisions are recorded at the same time throughout HF.

838 Cleaning algorithms are applied during event reconstruction so that all users have the same
839 starting point. A flexible software framework for the treatment of anomalous signals allows
840 one to apply the most up to date cleaning algorithms and to test new ideas. More aggressive
841 cleaning can be applied at the user analysis level. RBX/HPD noise is random and the overlap
842 with collision events is rare. It is easier to remove entire events identified as having high
843 channel multiplicity RBX/HPD noise than to introduce a large hole in the detector. Since some
844 exotic physics may mimic this signal we do not apply this level of cleaning by default.

845 As the event occupancy increases, cleaning algorithms that utilize energy isolation will be-
846 come less effective. Algorithms using time or the pulse shape will have to be further developed.

847 This will require a more precise understanding of the pulse shape as measured on the detector
848 and also an accurate simulation. Hardware upgrade options that would reduce the effect of
849 the PMT window interactions have been proposed and under evaluation. Improvements to
850 the simulation of noise are being developed.
