Acknowledgements

25 It is my pleasure to thank the many people who made this dissertation possible.

26 First of all, I would like to express my deep and sincere gratitude to my supervisor,
27 Professor Greg Landsberg. I thank him for his great guidance, assistance, stimulating
28 suggestions, and encouragement during these years of my research. His patience,
29 flexibility, and belief in me have boosted my confidence to become an independent
30 researcher.

31 Next, I would like to thank my Brown University's group for providing such a
32 wonderful working environment and for being so supportive to me during these years.
33 It was really a pleasure to be a part of the group. My special thanks to John Paul
34 Chou for all his help, for always being kind to answer all sorts of questions and giving
35 me valuable suggestions on my dissertation.

36 I am also grateful to my committee members, Professor David Cutts and Profes-
37 sor Chung-I Tan for spending their time to read my thesis and give me their valuable
38 advice and suggestions.

39 My special thanks to Quyen Nguyen and Vietnamese friends at Brown University
40 for their constant support and friendship.

41 Last but not least, to my parents and my little family, I owe the biggest debt of

42 gratitude. Without their unconditional love and consistent support over the years, I
43 would never have gotten this far.

44 Abstract of “ Search for Large Extra Dimensions in the Diphoton Final State at the
45 Large Hadron Collider ” by Duong Nguyen, Ph.D., Brown University, May 2011

46 We performed a search for large extra spatial dimensions via virtual graviton ex-
47 change in the diphoton channel with the Compact Muon Solenoid detector at the
48 Large Hadron Collider. No excess of events above the Standard Model predictions
49 has been found using a data sample collected in proton-proton collisions at the
50 $\sqrt{s} = 7$ TeV and corresponding to an integrated luminosity of approximately 36
51 pb^{-1} . New limits are set on the effective Planck scale in the range of 1.6-2.3 TeV, at
52 the 95% confidence level, depending on the number of extra dimensions. These are
53 the most restrictive bounds on models with more than two large extra dimensions
54 to date.

209 Chapter 1

210 Introduction

211 For nearly forty years, the Standard Model (SM) has proven to be a very successful
212 theory framework in particle physics. Its phenomenological predictions have been
213 confirmed by a variety of measurements upto TeV scale at fixed target, lepton and
214 hadron collider experiments. However, there are many unanswered questions in the
215 theoretical construction of the SM that make us believe that the SM is an incomplete
216 model. Furthermore, the existence of two fundamental scales that are so different
217 from each other results in the so-called hierarchy problem. This has led to the idea
218 of extending our 3+1 space-time dimensions to include additional compactified large
219 extra dimensions. This dissertation presents a search for the existence of these extra
220 dimensions at the Large Hadron Collider.

221 We begin this chapter with an overview about the SM and its history. After
222 that, we describe the hierarchy problem and one of its solutions, the Large Extra
223 Dimension paradigm. Finally, we review results from different experimental searches
224 for large extra dimensions.

225 1.1 The Standard Model of High Energy Physics

226 The Standard Model of high energy physics is a relativistic quantum field theory de-
227 scribing the interactions between fundamental particles. There are four known types
228 of interactions: gravitation, electromagnetic, weak and strong. The interactions act
229 between leptons and quarks via spin-1 intermediate vector bosons. The electromag-
230 netic and weak interactions are unified and described in a common framework called
231 the electroweak theory.

232 Leptons and quarks are fermions and are organized in 3 generations. The ques-
233 tion why there are three generation can not be answered by the Standard Model
234 itself. The photon, W and Z bosons, and gluons are responsible for transmitting the
235 electromagnetic, weak and strong interactions, respectively. Although the quantum
236 treatment of gravity is incomplete, the massless spin-2 graviton is considered the
237 gauge boson of the gravitational field and transmits the gravitational force. The
238 gravitational attraction is very small for microscopic particles compared to other
239 forces (10^{-29} weaker than the weak force). Therefore, it is usually ignored when
240 considering interactions between particles. However, its tiny strength raises a ques-
241 tion about the naturalness of the theoretical construction. This is referred to the
242 hierarchy problem of the SM.

243 Table 1.1 lists SM particles with six leptons and six quarks arranged in a 3-
244 generation structure. Beside the electric charge, quarks have an additional degree of
245 freedom called the color charge which is red (r), blue (b) or green (g). Note that for
246 each particle, there is an partner anti-particle which has the same mass, but opposite
247 electric and color charge.

248 The interactions between fundamental particles of the SM can be described by a

| Generation | Particle | Mass | Charge |
|------------|-------------------------------|-------------------------------|--------|
| Leptons | | | |
| 1 | Electron (e) | 0.5110 MeV/ c^2 | -1 |
| 1 | Electron neutrino (ν_e) | - | 0 |
| 2 | Muon (μ) | 105.6 MeV/ c^2 | -1 |
| 2 | Muon neutrino (ν_μ) | - | 0 |
| 3 | Tau (τ) | 1776.90 \pm 0.20 MeV/ c^2 | -1 |
| 3 | Tau neutrino (ν_τ) | - | 0 |
| Quarks | | | |
| 1 | Up (u) | 1.5-3.0 MeV/ c^2 | 2/3 |
| 1 | Down (d) | 3-7 MeV/ c^2 | -1/3 |
| 2 | Charm (c) | 1.25 \pm 0.09 GeV/ c^2 | 2/3 |
| 2 | Strange (s) | 95 \pm 0.25 MeV/ c^2 | -1/3 |
| 3 | Top (t) | 172.5 \pm 2.7 GeV/ c^2 | 2/3 |
| 3 | Bottom (b) | 4.20 \pm 0.07 GeV/ c^2 | -1/3 |

Table 1.1: Standard Model particles [1].

249 Lagrangian. In order to satisfy that the theory to be renormalizable, the Lagrangian
250 is required to be invariant under local gauge transformations. The local gauge trans-
251 formation belongs to a gauge symmetry group. The SM dynamical properties are
252 described by the $SU(3)_C \otimes SU(2)_L \otimes U(1)_Y$ gauge group structure, where C denotes
253 the color charge, L implies that SU(2) acts on the left-handed components and Y is
254 the weak hypercharge which relates to electric charge Q and the third component of
255 the weak isospin I_3 by the equation, $Y = 2(Q - I_3)$. The electroweak interaction is
256 described by the $SU(2)_L \otimes U(1)_Y$ sector while the strong interaction is described by
257 the $SU(3)$ gauge transformation group.

258 The local gauge invariant requirement on the Lagrangian introduces new fields
259 and their associated spin-1 gauge bosons. For the SU(2) gauge transformation,
260 the gauge fields are W_μ^i , $i = 1, \dots, 3$. The gauge field corresponding to the U(1)
261 transformation is B_μ . The $W_\mu^{1,2}$ gauge fields are combined to form the charge states

262 W_μ^+ , W_μ^- , which are identified as the physical W^\pm bosons, according to

$$W_\mu^\pm = \frac{-W_\mu^1 \pm iW_\mu^2}{\sqrt{2}} \quad (1.1)$$

$$W_\mu^0 = W_\mu^3 \quad (1.2)$$

263 The unification of the electromagnetic and weak interactions following the $SU(2) \otimes$
 264 $U(1)$ gauge group is expressed in the combination of B_μ and W_μ^3 :

$$A_\mu = \frac{g_2 B_\mu - g_1 Y_L W_\mu^3}{\sqrt{g_2^2 + g_1^2 Y_L^2}} \quad (1.3)$$

$$Z_\mu = \frac{g_1 Y_L B_\mu + g_2 W_\mu^3}{\sqrt{g_2^2 + g_1^2 Y_L^2}} \quad (1.4)$$

265 where Y_L is the left-handed projection of the hypercharge Y , for which $Y_L = -1$, g_1
 266 and g_2 are the coupling constants of the $U(1)$ and $SU(2)$ fields, A_μ and Z_μ correspond
 267 to massless photon and neutral boson Z , respectively. Defining $\sin\theta_w = g_1/\sqrt{g_1^2 + g_2^2}$,
 268 where θ_w is the Weinberg angle ($\sin^2\theta_w \sim 0.23$), we have:

$$g_1 = \frac{e}{\cos\theta_w} \quad g_2 = \frac{e}{\sin\theta_w} \quad g_Z = \frac{e}{\sin\theta_w \cos\theta_w} \quad (1.5)$$

$$A_\mu = W_\mu^3 \sin\theta_w - B_\mu \cos\theta_w \quad Z_\mu = W_\mu^3 \cos\theta_w + B_\mu \sin\theta_w \quad (1.6)$$

269 where e is the electromagnetic coupling constant or the electric charge, and g_Z is the
 270 coupling constant of Z_μ field.

271 Local gauge invariant requires the bosons to be massless. However, experiment
 272 measurements exclude this for the W and Z bosons. Therefore, the symmetry is not
 273 exact, but it is spontaneous broken by the Higgs mechanism to give mass to the
 274 gauges bosons. At the leading order, the SM predicts that $M_W/M_Z = \cos\theta_w$.

275 Quarks and leptons are arranged into left-handed doublets and right-handed

276 singlets. For example, the first generation lepton doublet is (ν_{eL}, e_L) and the singlet is
 277 e_R . For leptons, the charge current weak interaction transmitted by W^\pm gives strictly
 278 transitions within a generation. For quark doublets, generational mixing occurs for
 279 example (u_L, d'_L) , $d'_L = d_L \cos\theta_C + s_L \sin\theta_C$. Therefore, the charge-changing transition
 280 happens between generations. The neutral- current interaction is transmitted by the
 281 Z boson without charge changing. This interaction transmutes the doublet and the
 282 singlet members into themselves.

283 The SU(3) group of local gauge transformation, which changes the color, has eight
 284 generators corresponding to eight G_μ^a fields (a=1,...,8). Therefore, there are eight
 285 massless gauge bosons carrying pair of color labels, called the gluons. The strength
 286 of strong interaction varies with distances. It is weak at short distances but strong
 287 at large distances. This feature is called asymptotic freedom and it is explained
 288 why quarks are confined inside hadrons. Furthermore, since gluons carry color, they
 289 couple directly to each other. Therefore, calculations in quantum chromodynamic
 290 (QCD) theory are very challenging. Table 1.2 summarizes the gauge boson of the
 SM.

| Particle | Interaction | Mass (GeV/ c^2) | Charge (e) |
|---------------------|-----------------|--------------------|------------|
| Photon (γ) | Electromagnetic | 0 | 0 |
| W^\pm | Weak | 80.2 | ± 1 |
| Z | Weak | 91.2 | 0 |

Table 1.2: SM gauge bosons.

291

292 The SM was developed in 1960s and the early 1970s. Sheldon Glashow pro-
 293 posed the unification of the electromagnetic and the weak forces in 1963 [18]. The
 294 Higgs mechanism was incorporated in the electroweak model in 1967 by Steven
 295 Weinberg [19] and Abdus Salam [20]. Gerard 't Hooft showed that gauge theories
 296 are renormalizable in 1971 [21]. The QCD theory was completed by David Gross,

297 Frank Wilczek and David Politzer with the discovery of the asymptotic freedom in
 298 1973 [22, 23]. In the same year, Kobayashi and Maskawa proposed three genera-
 299 tion structure of the SM. However, the missing members of the third generation was
 300 observed recently in 1995 for top quark [24, 25] and in 2001 for tau neutrino [26].

301 1.2 Hard Scattering Cross Section

302 The LHC is a proton-proton collider. The proton quantum numbers suggest that
 303 protons are the bound state of uud valance quarks. They are also composed of
 304 radiated gluons and a sea of quark-antiquark pairs. These constitutions are called
 305 partons. Because the QCD coupling runs with the momentum transfer, or energy,
 306 scale of the parton-parton (Q) interaction and it is strong at low Q , the perturbation
 307 calculation at low Q is invalid. In general, the coupling constant is determined by
 308 the β -function. If one limits the QCD perturbative expansion of this function at the
 309 lowest order coefficient, the coupling constant $\alpha_s(Q^2)$ is defined as [?]:

$$\alpha_S(Q^2) = \frac{\alpha_S(\mu^2)}{1 + \frac{33-2n_f}{12\pi}\alpha_S(\mu^2)\ln(Q^2/\mu^2)} \quad (1.7)$$

310 Where μ is the renormalization scale at which a subtraction is performed to remove
 311 the ultraviolet divergences in the renormalization procedure. This parameter is cho-
 312 sen arbitrarily. A convenient choice is $\mu = M_Z$ which is large enough to be in the
 313 perturbative domain. Ref. [27] quotes:

$$\alpha_s(M_Z^2) = 0.1184 \pm 0.0007 \quad (1.8)$$

314 Historically, a dimensionful parameter $\Lambda_{QCD} \sim 200$ MeV is introduced directly to the
 315 definition of $\alpha_S(Q^2)$. This is the value where the coupling would diverge. However,

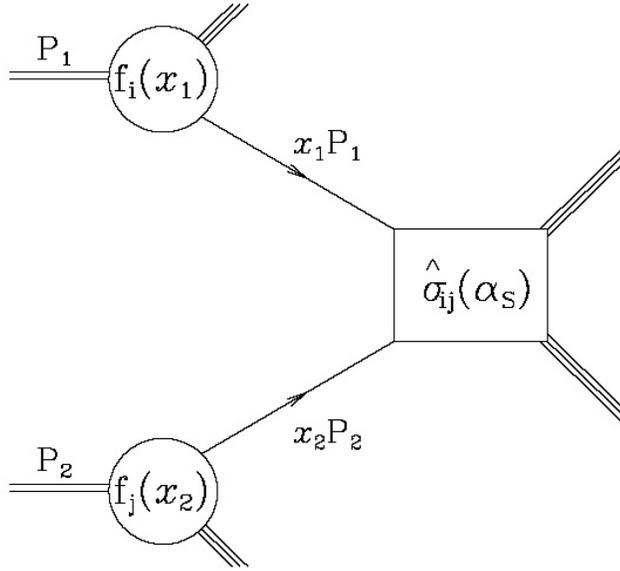

Figure 1.1: The parton model description of a hard scattering process [4].

316 this choice has some disadvantages: it is not dimensionless, depends on the number
 317 of active flavours, n_f , and on the renormalization scheme.

318 In hard scattering or high Q processes, the cross sections are factorized based on
 319 the factorization theorem of QCD [28]:

$$\sigma(P_1, P_2) = \sum_{i,j} \int dx_1 dx_2 f_i(x_1, \mu_F^2) f_j(x_2, \mu_F^2) \hat{\sigma}_{ij}(p_1, p_2, \alpha_S(\mu_R^2), Q^2/\mu_F^2) \quad (1.9)$$

320 where P_1, P_2 is the four-momenta of incoming hadrons, $p_1 = x_1 P_1, p_2 = x_2 P_2$ are
 321 the four-momentum of partons participating in the hard interaction, $f_{i,j}(x, \mu_F^2)$ are
 322 the parton (gluon or quark) distribution function (PDF) defined at a factorization
 323 scale μ_F , and $\hat{\sigma}_{ij}$ is the short-distance cross section for the scattering of the partons
 324 i and j . Because the coupling constant is small at high energy, this cross section is
 325 calculated as a perturbation series of the running coupling α_S .

326 The factorization factor is an arbitrary parameter which separates the long- and

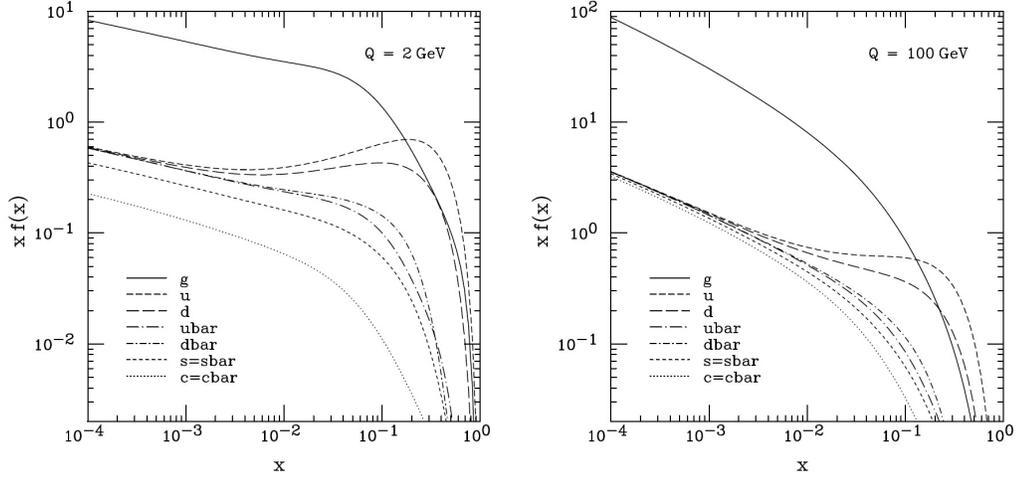

Figure 1.2: The CTEQ6M parton distribution functions at $Q = 2$ and 100 GeV [5].

327 short-distance calculation. If a emitted parton has transverse momentum less than
 328 μ_F , it is considered as a part of the hadron structure and is absorbed into the parton
 329 distribution function. In contrast, a high transverse momentum parton is a part of
 330 the short-distance cross section. The dependence of cross section on μ_F is weaker if
 331 more terms are included in the perturbative expansion.

332 The PDFs are the probability density to find a parton inside of the proton with a
 333 given fraction of the total momentum. It is determined from experimental measure-
 334 ments. An example of these functions are calculated by CTEQ collaboration based
 335 on QCD studies at HERA and the Tevatron. Both the parton distribution functions
 336 and short-distance cross section, $\hat{\sigma}$, depend on the scales. Therefore, the scales need
 337 to be used consistently in the PDF and the short-distance calculation. Otherwise,
 338 cancellation of ultraviolet and collinear divergences do not meet. A common setup
 339 for scales is $Q^2 = \mu_R^2 = \mu_F^2$.

340 1.3 The Direct Photon Production

341 Direct photons are photons produced in the parton-parton collisions, which distin-
 342 guish to photons from decays of neutral hadrons (for example π_0). A photon is
 343 created in association with jets in the Compton process ($qg \rightarrow \gamma q$) or annihilation
 344 process ($q\bar{q} \rightarrow \gamma q$) (see Figure 1.3). These are leading order perturbation contribu-
 345 tions in the cross section calculation ($O(\alpha\alpha_S)$, α and α_S are the electromagnetic and
 strong couplings, respectively).

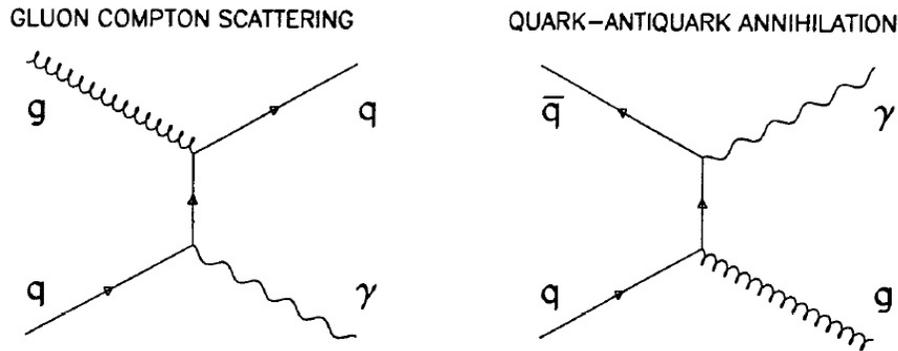

Figure 1.3: Leading order Feynman diagram of gamma+jet process.

346

347 Photon pairs are also produced in proton-proton collisions. The LO cross section
 348 ($O(\alpha^2)$) comes from the quark-antiquark annihilation ($q\bar{q} \rightarrow \gamma\gamma$). The diagram is
 349 called the Born diagram (diagram a in Figure 1.4). Diagrams d and g in Figure 1.5
 350 show the one and two fragment processes where one or both photons come from the
 351 collinear fragmentation of hadrons. These diagrams are also at LO. The next-to-
 352 leading order diagrams include real (diagram b in Figure 1.5) or virtual (diagram
 353 c in Figure 1.5) corrections, which are $O(\alpha_S)$, to the LO Born diagram. Therefore,
 354 the total NLO contribution is $O(\alpha_2\alpha_S)$. The corresponding NLO fragmentation
 355 processes are shown in Figure 1.5, diagrams e, f, h, i.

356 There are multi collinear singularities in the fragmentation diagrams when a

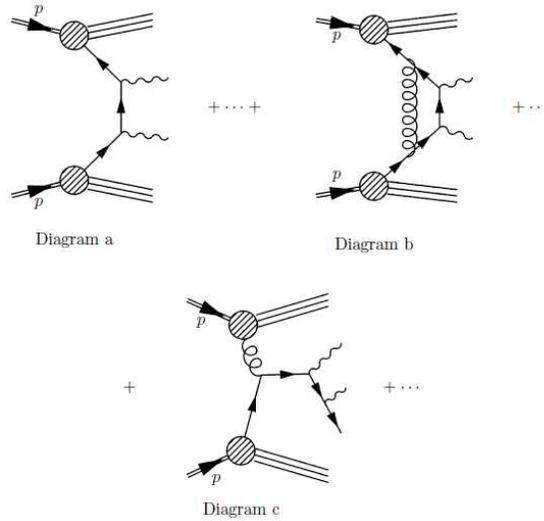

Figure 1.4: The direct contributions to the diphoton cross section. Diagram a: the LO Born process. Diagram b and c: the NLO processes

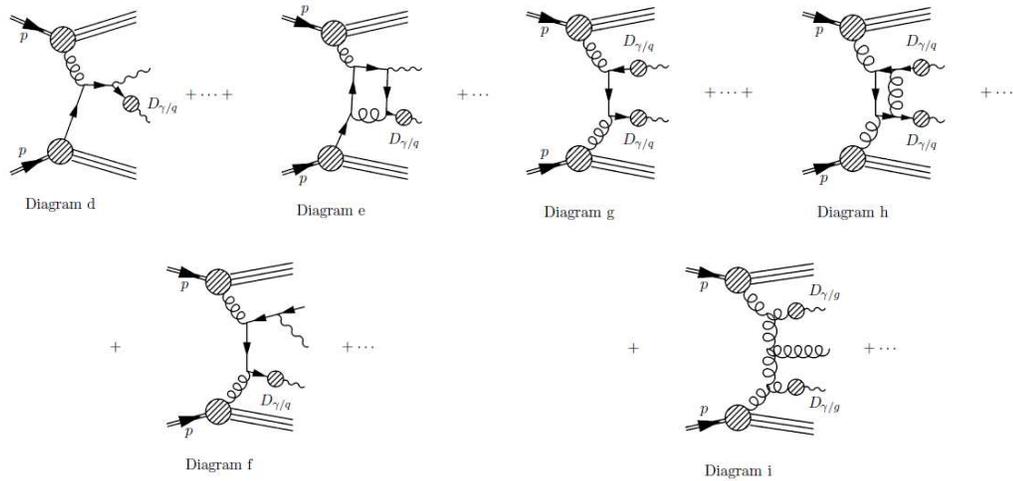

Figure 1.5: The fragmentation contributions to the diphoton cross section. Diagrams d and g: the LO processes. Diagrams e, f, h, i: the corresponding NLO processes. $D_{\gamma/q \text{ or } g}$ is the fragmentation function which absorbs the quark-photon singularity

357 high p_T parton undergoes a cascade of successive collinear splittings ending up with a
 358 parton-photon collinear splitting (momenta of photon and parton are nearly parallel).
 359 These singularities are absorbed into a photon "fragmentation function" $D_{\gamma/q,g}(z, \mu^2)$
 360 representing the probability of finding a photon carrying a longitudinal momentum
 361 fraction z in a quark or gluon jet at a scale μ . If this scale, often chosen at the order
 362 of the hard scale of the process, is large compared to any typical hadronic scale

363 (~ 1 GeV), these functions have a size of roughly $\alpha/\alpha_S(\mu)$. Therefore, they com-
 364 pensate the strong interaction vertex contribution, which is $O(\alpha_S)$, in cross section
 calculation.

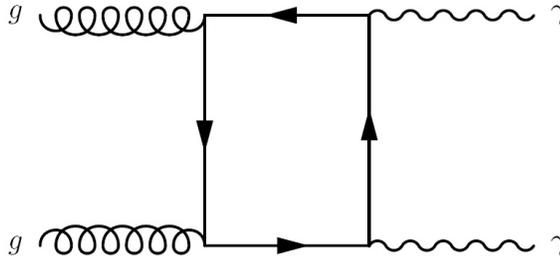

Figure 1.6: The box diagram

365

366 Finally, the gluon-gluon fusion process or box diagram is at the NNLO (next-to-
 367 next-to-leading order) level suppressed by $O(\alpha_S^2)$. However, it is often included in
 368 the calculations of the xs at the LHC due to the high gluon luminosity.

369 1.4 The Hierarchy Problem and Large Extra Di- 370 mensions Paradigm

371 The hierarchy problem refers to the enormous difference between the electroweak
 372 symmetry breaking scale, $M_{EWSB} \sim 10^3$ GeV, and the fundamental scale of gravity,
 373 $M_{Pl} \sim 10^{19}$ GeV. The consequence of this large difference in scale is that a very high
 374 degree of fine-tuning is required to protect the Higgs mass from radiative corrections.
 375 For example, the correction for Higgs mass from fermi loops (Figure 1.7) is given by:

$$\Delta M_H^2 = \frac{\lambda_f^2}{4\pi^2} (\Lambda^2 + M_H^2) + \dots \quad (1.10)$$

376 where Λ is the ultraviolet cutoff and λ_f is the self coupling constant of the Higgs
 377 bosons. If Λ is at the order of M_{Pl} , the constraint of Higgs mass at ~ 100 GeV requires
 378 the fine tuning or cancellation of various loops to a precision of $\sim (M_H/\Lambda)^2 \sim 10^{-34}$.

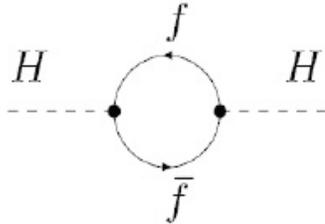

Figure 1.7: The fermion loop correction to Higgs mass

379

380 In 1998, Arkani-Hamed, Dimopoulos and Dvali (ADD) proposed the Large Extra
 381 Dimensions paradigm to solve the hierarchy problem [29]. In this framework, the
 382 SM particles and gauge interactions are constrained to the common $3 + 1$ space-time
 383 dimensions, while gravity is free to propagate through the entire multidimensional
 384 space (bulk). Therefore, the gravitational force is effectively diluted, and it appears
 385 to be weak (strength order $\sim 1/M_{Pl}$) for an observer in the SM brane. For instance,
 386 suppose that there are n extra compact spatial dimensions of the same radius $\sim R$. By
 387 applying the Gauss's law in $(4+n)$ dimensions, the gravitational potential between
 388 two test masses, m_1, m_2 separated by a distance of $r \ll R$ is[29]

$$V(r) \sim \frac{m_1 \times m_2}{M_D^{n+2}} \frac{1}{r^{n+1}}, (r \ll R) \quad (1.11)$$

389 where M_D is the fundamental Plank scale of a $(4+n)$ dimensional theory. If two
 390 masses are separated by $r \ll R$, their gravitational flux lines can not continue to
 391 penetrate in the extra dimensions. Therefore, the potential is:

$$V(r) \sim \frac{m_1 \times m_2}{M_D^{n+2} R^n} \frac{1}{r}, (r \gg R) \quad (1.12)$$

392 Compared to the Newtonian gravitational potential, our effective M_{Pl} is:

$$M_{Pl}^2 \sim M_D^{n+2} R^n \quad (1.13)$$

393 If we set $M_D \sim M_{EW} \sim 1$ TeV, we find that

$$R \sim 10^{\frac{30}{n_{ED}} - 19} \text{ m}. \quad (1.14)$$

394 $n_{ED} = 1$ case is excluded because R is approximately 10^{11} m which is on the order of
 395 the radius of the Solar system. For $n_{ED} = 2$, $R < 10^{-2}$ cm, which is out of the reach
 396 of direct measurements of gravity at short distances[30] (as of 1998, gravitational
 397 measurements are not sensible to the distance smaller than 1 mm). For $n_{ED} = 6$
 398 or 7 (corresponding to the 10 or 11-dimension space-time suggested by the string
 399 theory), the size of the extra dimensions is ~ 1 fm, which is fairly large compared
 400 to Plank or electroweak lengths; hence, the name Large Extra Dimensions.

401 An enhancement of the gravitation in the case of extra dimensions can be ex-
 402 plained in a manner similar to the "particle-in-box" problem. Because gravitons
 403 propagate in the compact extra dimensions, the boundary conditions result in a
 404 quantization of the graviton's energy into discrete eigenvalues. From the point of
 405 view of a 3-dimensional observer, they look like a tower of graviton excitations,
 406 referred to Kaluza-Klein modes. Since the energy spacing between modes is very
 407 small ($\sim 1 - 100 \text{ meV}$ given the size of EDs $\sim 10^{-3} - 10^{-15}$ m), there are many KK
 408 modes to be excited at high energy. Although each KK mode couples to the energy-
 409 momentum tensor with the gravitational strength $G_N \sim 1/M_{Pl}^2$, the large number
 410 of these modes is sufficient to enhance the gravitational coupling tremendously. For
 411 example, at the energy of 1 TeV, given the size of ED ~ 1 fm and $n_{ED} = 7$, as many
 412 as 10^{28} modes can be excited [31].

413 The requirement that all particles except gravitons are constrained to the SM
 414 brane and must not feel the extra space satisfies constraints from atomic physics
 415 and other experimental data. Although the ADD paradigm solves the hierarchy
 416 problem by suggesting a fundamental Plank scale of the order of EW scale in the
 417 multidimensional space, it converts the energy hierarchy to a distance hierarchy since
 418 the size of the extra dimensional space is much larger than the range of EWSB energy
 419 scale (about 10^{-19} m). With the existence of extra dimensions, the electroweak scale
 420 is the only fundamental scale in nature where the gravitational and gauge interactions
 421 unite. Thus, the Plank scale is not the fundamental scale, but its enormity is due to
 422 the large size of the new dimensions.

423 1.5 Searches for Large Extra Dimensions at Col- 424 liders

425 The production of KK gravitons (G_{KK}) at colliders is possible since gravitons couple
 426 to the energy-momentum tensor. This implies that graviton can be added to any ver-
 427 tices or lines of SM Feynman diagrams. One can look for the graviton emission which
 428 results in a single jet or a gauge boson associated with a large missing transverse
 429 energy due to escapes of gravitons to the extra dimension space. Direct graviton
 430 emissions depend directly to the fundamental Plank scale M_D . However, it is ex-
 431 pected to be suppressed by a factor $(\sqrt{\hat{s}}/M_D)^{n_{ED}+2}$, where $\sqrt{\hat{s}}$ is the characteristic
 432 center-of-mass energy at which the effects of EDs are most pronounced. Further-
 433 more, the dependence on the number of extra dimensions for the virtual graviton
 434 effects is fairly weak [32, 33]. An other channel to look for ED effect is the virtual
 435 graviton production via Drell-Yan like processes. Subsequently, gravitons decay to

436 two photons or fermions. The later is less sensitive because decays of spin 2 gravitons
 437 to spin 1/2 fermions is suppressed in the s-wave mode. The virtual graviton channel
 438 is a complement to the direct graviton emission channel because it depends on the
 439 ultra violet cutoff M_S of the KK spectrum. M_S is general lower than M_D , so the
 extra dimension effect might be firstly seen in the virtual graviton channel.

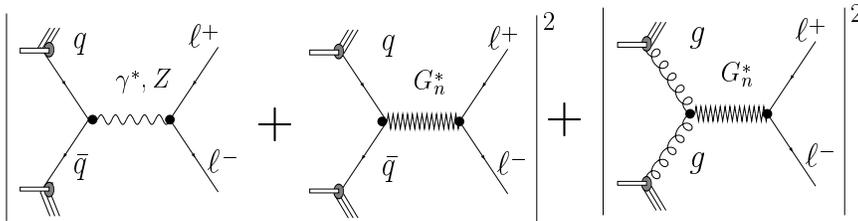

Figure 1.8: DY production Feynman diagrams including the large extra dimensions [6].

440

441 The virtual graviton exchange diagrams interfere with their SM counterparts as
 442 shown in Figure 1.8 for the DY production. The consequence of additional con-
 443 tributions from these diagrams is an enhancement in DY or diboson spectrum at
 444 high invariant masses. The cross section of virtual graviton exchange is not well-
 445 defined since it depends on a particular representation of the interaction Lagrangian
 446 and the definition of the ultraviolet cutoff on the KK modes. There are three such
 447 representations [32, 33, 34]. All of them use a variable $\eta_G = \mathcal{F}/M_S^4$, where \mathcal{F} is a
 448 dimensionless parameter, and M_S is the ultraviolet cutoff, to parameterize the total
 449 or differential cross section with contribution from the G_{KK} exchange:

$$\sigma_{\text{tot}} = \sigma_{\text{SM}} + \eta_G \sigma_{\text{int}} + \eta_G^2 \sigma_G, \quad (1.15)$$

450 where σ_{SM} is the SM cross section, σ_{int} is the interference term and σ_G is the pure
 451 gravitational effect term.

452 The parameter \mathcal{F} contain the dependence of virtual G_{KK} exchange effect on the
 453 number of extra dimensions. These are its definitions used in each representation

454 mentioned above:

$$\mathcal{F} = 1, \text{ (GRW [32]);} \tag{1.16}$$

$$\mathcal{F} = \begin{cases} \log\left(\frac{M_S^2}{M^2}\right), & n = 2 \\ \frac{2}{n-2}, & n > 2 \end{cases}, \text{ (HLZ [34]);} \tag{1.17}$$

$$\mathcal{F} = \frac{2\lambda}{\pi} = \pm \frac{2}{\pi}, \text{ (Hewett [33]).} \tag{1.18}$$

455 In the above formula, \mathcal{F} depends explicitly on the number of EDs only in the HLZ
 456 formalism. The gravity effect contributes constructively in both HLZ and GRW
 457 formalism. However, the sign of \mathcal{F} is unknown and included in a parameter λ in
 458 Hewett convention. λ is of order 1 and usually assigned either +1 (constructive
 459 interference) or -1 (destructive interference).

460 1.6 Current Constraints and Limits

461 Search for extra dimensions have been performed by many experiments and the
 462 model parameters are also constrained by astrophysical observations and cosmology.
 463 One of the most straightforward approaches is to measure the gravity directly at short
 464 distances and look for modification of Newton's gravitational law. This modification
 465 is parameterized by the Yukawa potential.

$$V(r) = -G \frac{m_1 m_2}{r} (1 + \alpha e^{-r/\lambda}) \tag{1.19}$$

466 These measurements are sensitive to distances $\sim 50\mu\text{m}$ with the current techniques.
 467 If all extra dimensions have the same sizes, this limit implies that these measurements
 468 can not go beyond $n = 2$ case. However, only the total volume of extra dimensions

469 is necessary, not the shape of extra dimensions. Therefore, one of extra dimensions
 470 might be macroscopic and sensitive to direct measurements probing $n > 2$ cases. The
 471 best limit on the size of extra dimensions is given by Eöt-Washington group [35],
 472 which is $R < 0.44 \mu\text{m}$ at 95% CL. This limit corresponds to $M_D > 3.2 \text{ TeV}$ for two
 extra dimensions of equal sizes [7].

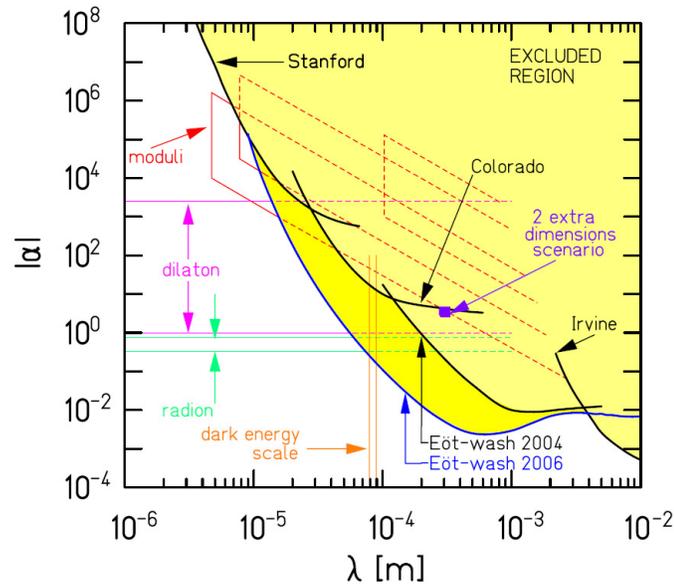

Figure 1.9: Constraints on Yukawa violations of the gravitational $1/r^2$ law. The shaded region is excluded at the 95% confidence level [7].

473

474 An example of constraining ADD model using astrophysical observations comes
 475 from the observation of a handful of neutrinos from SN1987A explosion by IMB and
 476 Kamiokande detectors. This method is based on the assumption that KK graviton
 477 emission is an competitive cooling mechanism for the supernovae; thus the dominant
 478 SM mechanism, the neutrino emission is suppressed. The constraints on M_D found
 479 are $M_D > 25 - 30 \text{ GeV}$ for $n = 2$ and 2-4 TeV for $n = 3$ and below 1 TeV for any
 480 higher number of extra dimensions [36]. In general, the limits from astrophysical
 481 observation and cosmology are strong (up to 1700 TeV) for $n = 2$, moderate (few
 482 TeV) for $n = 3$, and rather weak for $n > 3$ [31]. The uncertainties in predictions are

Table 1.3: 95% CL lower limits on the fundamental Planck scale M_D (in TeV) from Tevatron experiments [2].

| Experiment and channel | $n = 2$ | $n = 3$ | $n = 4$ | $n = 5$ | $n = 6$ |
|--|---------|---------|---------|---------|---------|

483 large due to high uncertainties of the astrophysical measurements.

484 At colliders, LEP experiments searched for extra dimension in both direct gravi-
 485 ton emission channel via $e^+e^- \rightarrow \gamma/Z + G_{KK}$ and virtual graviton production via
 486 fermions or diboson channels. However, the $e^+e^- \rightarrow \gamma + G_{KK}$ and the $e^+e^- \rightarrow$
 487 $e^+e^-/\gamma\gamma$ channels are the most sensitive. D0 and CDF collaboration also searched
 488 for gravitational effect in virtual graviton production, monojet and monophotons
 489 channels. The most recent 95% limits using $1\text{-}3 \text{ fb}^{-1}$ data from those searches are
 490 presented in Table 1.4. CDF gives the most stringent limits on M_D in the combined
 491 monojet and monophoton channel. The best M_S limits comes from D0 using the
 492 combined $ee + \gamma\gamma$ channel. D0 also performed for the first time the search in the
 493 dijet channel.

494 Chapter 2

495 Experimental Apparatus

496 The Large Hadron Collider (LHC) is the highest energy hadron collider to date,
497 which collides proton-proton beams at the designed center of mass energy of 14 TeV.
498 In 2010, when the analysis presented in this dissertation, was carried out, the center-
499 of-mass energy of the proton-proton collisions is 7 TeV. The Compact Muon Solenoid
500 (CMS) detector, located at Point 5, measures the outcomes of the collisions. The
501 data collected by CMS are used in a search for large extra dimensions presented in
502 this dissertation. The LHC accelerator complex and the CMS detector are described
503 in Section 2.1 and Section 2.2, respectively.

504 2.1 The Large Hadron Collider

505 The Large Hadron Collider (LHC) is a hadron accelerator complex located at the Eu-
506 ropean Organization for Nuclear Research (CERN), Switzerland [3, 8]. It is designed
507 to accelerate proton or heavy ion beams using two main circular acceleration rings

508 with a circumference of 27 km inside the LEP (Large Electron Positron) tunnel. In
 509 order to reach the design collision center-of-mass energy, 14 TeV, the proton beams
 510 are accelerated through subsequent steps as shown in Figure 2.1 (left). The proton
 511 beams are injected to the Proton Synchrotron (PS) from the linear accelerator and
 512 accelerated to 25 GeV before being injected to the Super Proton Synchrotron (SPS).
 513 The SPS raises their energy to 450 GeV. Finally, the beams are injected to the main
 514 LHC rings and circulate in opposite directions until reaching the nominal energy.
 515 The beams collide at 4 interaction points where the ALICE (An LHC Heavy Ion Ex-
 516 periment), ATLAS (A Toroidal LHC Apparatus), CMS (Compact Muon Solenoid),
 517 and LHCb (LHC beauty experiment) experiments are located. Figure 2.1 (right)
 518 shows the basic layout of the LHC main ring which has eight arcs and eight straight
 519 sections (about 528 m long each). The experiments are located at the straight sec-
 520 tions. ATLAS and CMS are the two high-luminosity experiments located at Point 1
 521 and Point 5, respectively.

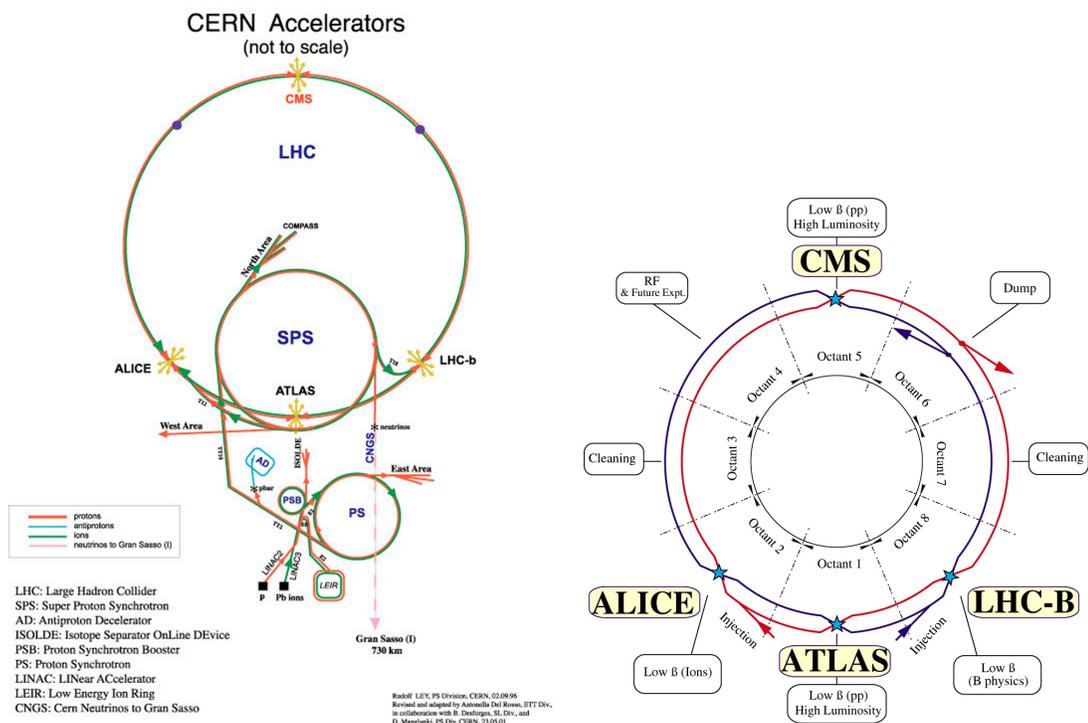

Figure 2.1: The LHC accelerator complex (left) and the main ring layout (right)

522 At design, the beams are packed in a large number of closely spaced bunches,
 523 3564 in total along the LHC orbit, and separated in time by 25 ns (approximately
 524 7.5 m). However, only 2835 bunches are used for collisions with detailed structure
 525 decided by the injection scheme and the properties of the dump system. The beams
 526 cross each other by a small angle at the interaction points (200 μ rad) in order to
 527 avoid unwanted collisions [3]. The luminosity is given by:

$$L = \frac{N^2 k_b \gamma}{4\pi \epsilon_n \beta^*} F, \quad (2.1)$$

528 where N is the number of protons per bunch, k_b is the number of bunches, f is the
 529 revolution frequency, γ is the relativistic factor, ϵ_n is the normalized transverse emit-
 530 tance, β^* is the beta function value at the interaction point, and F is the reduction
 531 factor caused by the crossing angle (~ 0.9 at the LHC). Table 2.1 lists the nominal
 532 values of those parameters for the design instantaneous luminosity $L = 10^{34} \text{ cm}^{-2}\text{s}^{-1}$.

| N | k_b | f | ϵ_n | β^* |
|-----------------------|-------|---------|-----------------------------------|-----------|
| 1.15×10^{11} | 2835 | 400 MHz | 3.75 $\mu\text{m}\cdot\text{rad}$ | 0.5 m |

Table 2.1: LHC designed parameters[3]

533

534 The LHC NbTi superconducting magnets are designed to maintain an 8 T field.
 535 They are cooled by superfluid helium at a temperature below 2 K. The main part of
 536 the LHC rings contains 1232 two-in-one dipoles. As shown in Figure 2.2, two beams
 537 are kept in separated dipoles in the same cryostat. There are also quadrupole and
 538 multipole magnets to focus and stabilize the beams, respectively.

539 The first collisions at the LHC took place in November 2009 with an energy of
 540 450 GeV per beam. The energy increased to 1.18 TeV per beam in December 2009
 541 and later to 3.5 TeV in March 2010 which was maintained during 2010 run. The

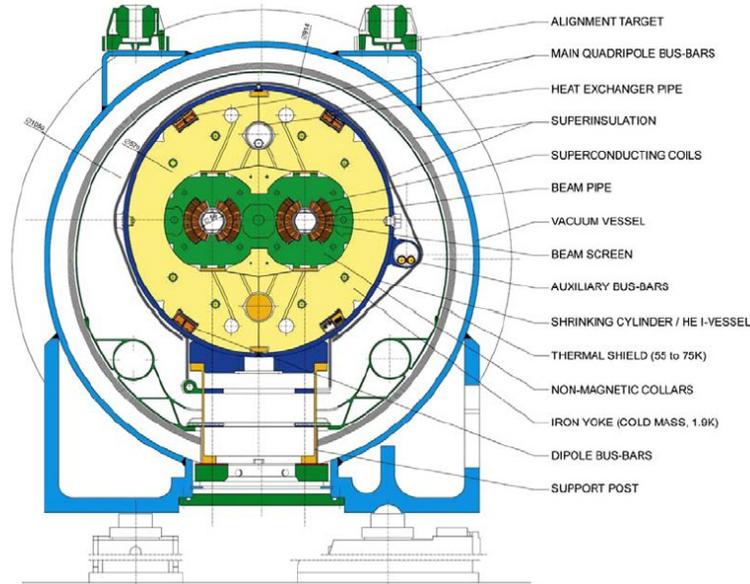

Figure 2.2: Cross section of a LHC dipole [8].

542 LHC will continue running at this energy in 2011. The instantaneous luminosity
 543 increased from $10^{27} \text{ cm}^{-2}\text{s}^{-1}$ in March 2010 to its peak, $2 \times 10^{32} \text{ cm}^{-2}\text{s}^{-1}$ in October
 544 2010. Figure 2.3 shows the integrated luminosity evolution of LHC in 2010. The
 545 integrated luminosity increased steeply toward the end of the run, and the LHC
 546 delivered a total of 47 pb^{-1} of collision data in 2010.

547 2.2 The CMS Detector

548 2.2.1 Overview

549 CMS uses a right-handed coordinate system, where the x -axis points radially inward
 550 toward the center of the LHC, the y -axis points vertically upward, and the z -axis
 551 points along the counter-clockwise beam direction (toward the Jura mountains from
 552 the LHC Point 5). We measure the polar angle θ with respect to the z -axis and define

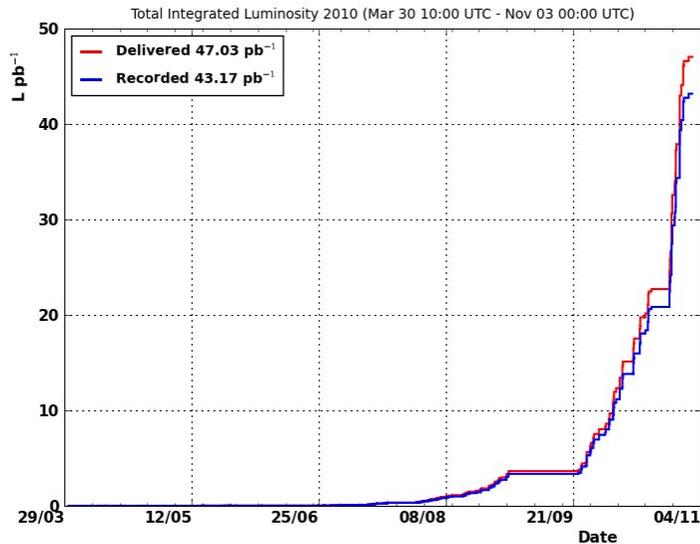

Figure 2.3: The integrated luminosity evolution in 2010 at CMS.

553 the pseudorapidity $\eta \equiv -\ln \tan(\theta/2)$. The azimuthal angle, ϕ , is measured with
 554 respect to the x -axis. The transverse quantities, for example transverse momentum
 555 or energy, are measured in the plane transverse to the beam direction. Thus, they
 556 are calculated from the x and y components.

557 The CMS detector is a multi-purpose detector designed to perform a wide range of
 558 high-energy collider physics at the LHC [37]. It is 21.6 m long, 14.6 m in diameter,
 559 and the total weight of 12500 t. It is located in the collision hall about 100 m
 560 underground at Point 5. Despite its huge size, the design of the CMS detector
 561 is compact compared to the ATLAS detector, with all subdetectors closely installed
 562 about a large-bore superconducting solenoid. The superconducting solenoid operates
 563 at 3.8 Tesla providing large bending power (~ 12 Tm). It is 13m long, and 6 m in
 564 diameter which is large enough to contain the tracker and calorimeter systems.

565 The innermost subdetector is the all-silicon pixel detector whose purpose is to
 566 identify hits for track reconstruction. The 10-layer silicon microstrip detector, which

567 has a cylindrical shape of 5.8 m length and 2.6 m diameter is placed between the
 568 pixel detector and the electromagnetic calorimeter. The electromagnetic calorimeter
 569 (ECAL) covers up to $|\eta| \leq 3$ and is made of lead-tungstate scintillating crystals with
 570 the a thickness of 25 radiation lengths. The CMS hadronic calorimeter (HCAL)
 571 is placed after the ECAL with coverage up to $|\eta| \leq 5$. Finally, there are 4 muon
 572 stations installed outside the solenoid in the steel return yoke. This ensures robust
 muon track reconstruction and geometric coverage up to $|\eta| < 3$.

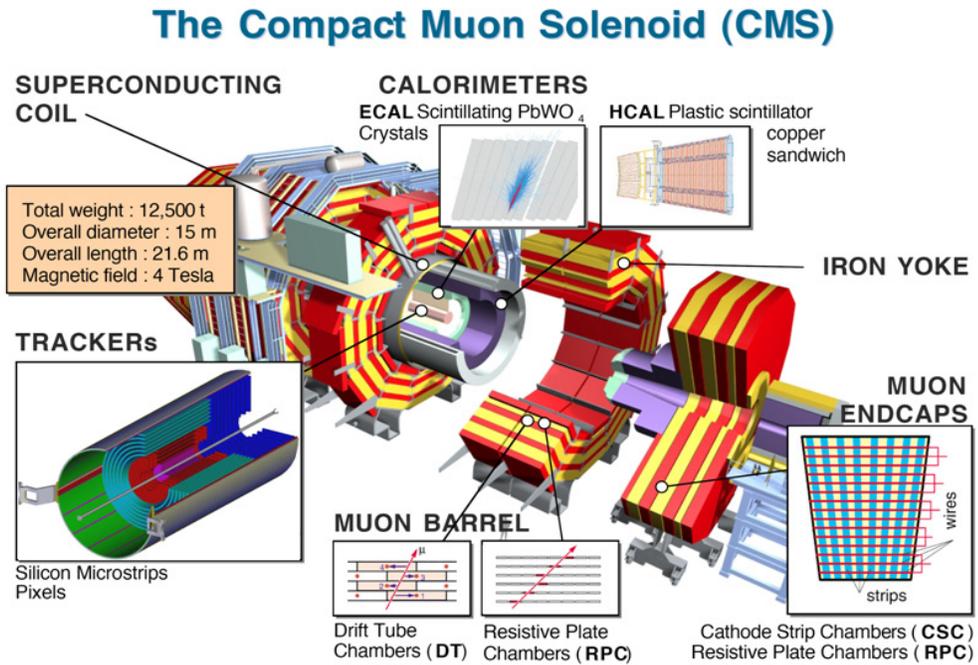

Figure 2.4: An overview of the CMS detector.

573

574 2.2.2 The Tracker

575 The LHC produces about 1000 particles traversing the tracker for every bunch cross-
 576 ing (~ 25 ns interval) at peak luminosity [37]. This requires a high- granularity and
 577 fast-response tracker to reliably reconstruct particle trajectories and vertices. Be-

578 cause of this, the CMS tracker is constructed entirely with silicon technology. The
 579 total active silicon area of CMS tracker is 200 m² and is composed of 1440 pixel
 580 and 15148 strip modules [37]. Figure 2.5 shows the layout of the CMS tracker. The
 maximum coverage of the tracker is $|\eta| \leq 2.5$. The pixel detector has 3 layers in the

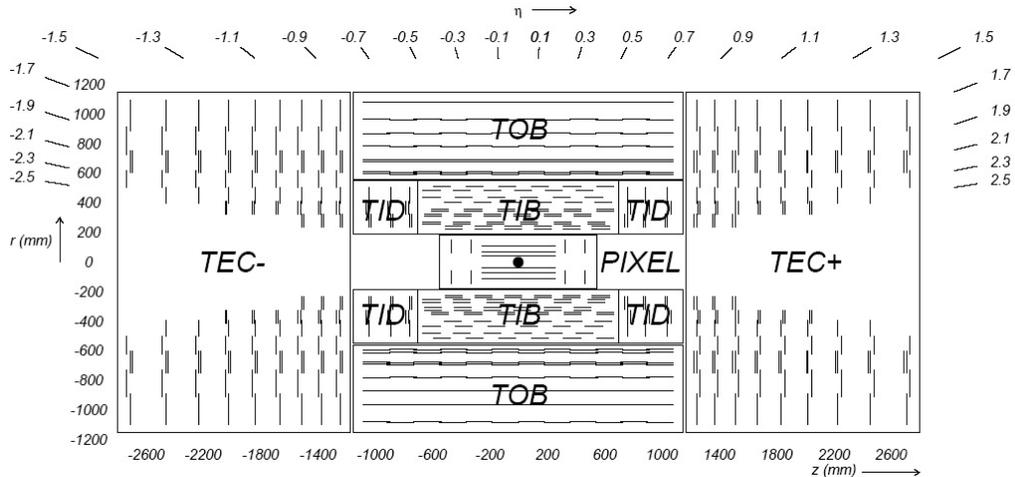

Figure 2.5: The tracker geometry.

581

582 barrel located between 4.4, 7.3 and 10.3 cm from the center of the detector. Each
 583 detector is 53 cm long. At the endcap, it is enclosed by 2 hollow disks with a ra-
 584 dius of 6 and 15 cm. The inner and outer disks are at $|z|=34.5$ cm and $|z|=46.5$
 585 cm, respectively. There are about 66 million hybrid pixel cells in an approximately
 586 $100 \times 150 \mu\text{m}$ square shape. Because of the high density of those small elements,
 587 the spatial resolution is approximate $10 \mu\text{m}$ in the $r-\phi$ plane and $20 \mu\text{m}$ in the z
 588 direction.

589 The pixel detector is surrounded by the silicon-strip detector. In the barrel, it
 590 includes the Tracker Inner Barrel (TIB) and the Tracker Outer Barrel (TOB). The
 591 TIB has 4 layers with a half length of 65 cm and the TOB has 10 layers covering 110
 592 cm in z at each side ($|z| < 220$ cm). The end cap region is covered by the Tracker
 593 End Cap (TEC) and the Tracker Inner Disks (TID). The 3-disk TID are embedded
 594 between the TIB and TEC. Each TEC is composed of 9 disks and extends the

595 longitudinal coverage from $|z|=120$ cm to $|z|=280$ cm.

596 The silicon-strip detector is built from 15148 modules of 24244 sensors with 9.3
 597 million strips. Depending on where the module is mounted, the strip pitch ranges
 598 from 80 to 180 μm . Some of the layers and rings (layers 1 and 2 for TIB and TOB;
 599 rings 1 and 2 for TID; rings 1, 2 and 5 for TECs) use a double-sided configuration
 600 in which two micro-strip detector modules are mounted back-to-back with a stereo
 601 angle of 100 mrad. The purpose is to measure a second coordinate (z in the barrel
 602 and r on the disks). The geometry arrangement of the tracker provides at least 9 hits
 603 in the strip detector with $|\eta| < 2.4$. Among these hits, at least 4 are two-dimensional
 604 measurements with a resolution of 230 and 530 μm in the TIB and TOB, respectively.

605 Figure 2.6 shows the expected resolutions of transverse momentum and recon-
 606 struction efficiency as a function of pseudorapidity for single muons with transverse
 607 momenta of 1, 10 and 100 GeV. The transverse resolution is less than 2% in the
 608 barrel and increases in the endcap. The reconstruction efficiency can be as good as
 99% for muon in much of the acceptance range.

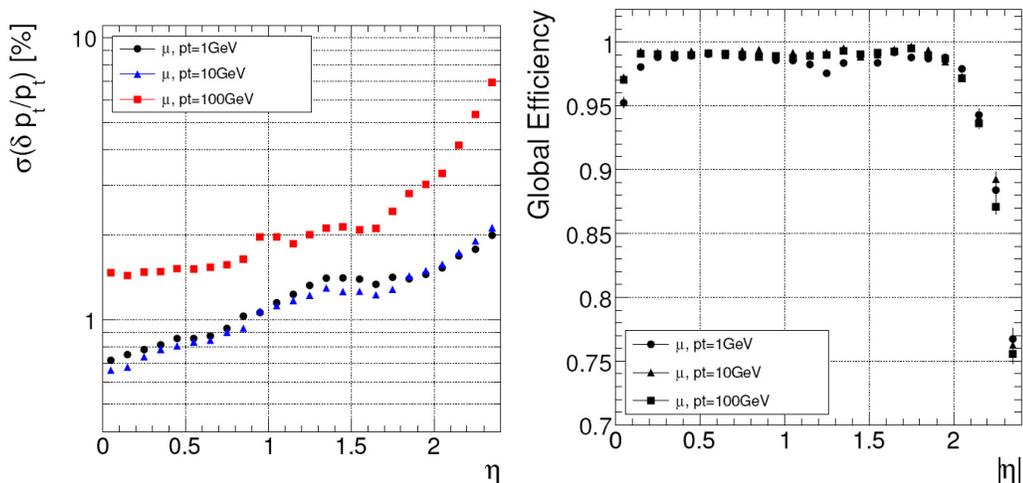

Figure 2.6: The tracker transverse momentum resolution and the muon reconstruction efficiency.

610 **2.2.3 The Electromagnetic Calorimeter**

611 The CMS electromagnetic calorimeter (ECAL) is a homogeneous scintillator calorimeter.
 612 It is built from 61200 crystals in the barrel and 7324 crystals in each of the two
 613 endcaps [37]. Crystals are made of fast and radiation-hard lead-tungstate (PbWO_4).
 614 In order to improve the position resolution of electrons and photons, a preshower
 615 detector is placed in front of the endcap crystals. Scintillator light is produced by
 616 PbWO_4 crystals and converted to electric pulses by avalanche photodiodes (APDs)
 617 in the barrel and vacuum phototriodes (VPTs) in the endcaps. The homogeneous
 618 ECAL calorimeters provides high granularity and excellent energy resolution, which
 619 makes detection of two photons from the postulated Higgs boson decay possible.

620 **ECAL layout and mechanic**

621 As shown in Figure 2.7, the CMS ECAL comprises 3 parts: the ECAL barrel (EB)
 622 covering $|\eta| < 1.479$, the ECAL endcaps (EE) extending from $1.497 < |\eta| < 3.0$ and
 623 the preshower detector placed in front of the ECAL endcaps. The EB is segmented
 624 by 360 folds in ϕ and 2×85 folds in η . The crystal front face centers are at a radius
 625 of 1.29 m. In order to avoid cracks aligned with particle trajectories, the crystal
 626 axes make a small angle (3°) with respect to the vector from a nominal interaction
 627 vertex, in both ϕ and η projections. In the EB, the crystals of each half-barrel are
 628 grouped in 18 supermodules (spanning 20° in ϕ). Each supermodule comprises four
 629 modules. The first module has 500 crystals and each of the 3 remaining modules
 630 contains 400 crystals. Inside a module, crystals are grouped in submodules of 2×5
 631 crystals to simplify the construction and assembly. The EE detector is identical in
 632 both sides. Each side is divided into 2 halves in a "D" ("Dee") shape. Each Dee has
 633 3662 crystals organized in groups of 5×5 crystals called the supercrystal. Therefore,

634 each Dee consists of 138 standard supercrystals and 18 special partial superclusters
 635 on the inner and outer circumferences.

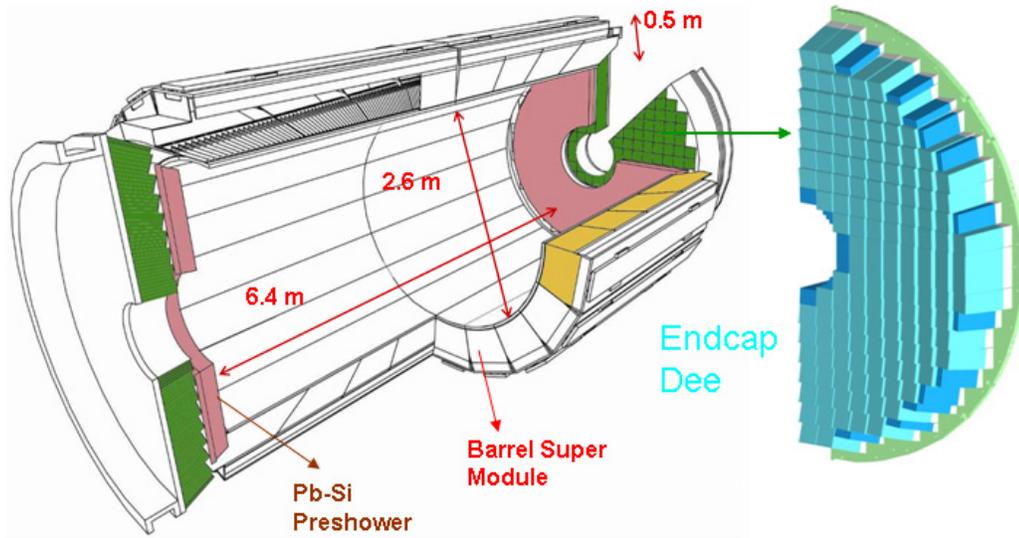

Figure 2.7: The ECAL layout.

636 Lead-tungstate crystals

637 The PbWO_4 crystal is an appropriate choice for building a fine granularity and a
 638 compact calorimeter. It has a high density (8.28 g/cm^3), a short radiation length
 639 (0.89 cm) and a small Molière radius (2.2 cm). Its scintillation time is short. About
 640 80% of the scintillation light is emitted in 25 ns , which is the LHC bunch crossing in-
 641 terval. However, the light output is relatively low and varies with temperature change
 642 ($-2.1\%^\circ\text{C}^{-1}$ at 18°C). The scintillation emission spectrum has a broad maximum at
 643 $\sim 420\text{-}430 \text{ }\mu\text{m}$, which matches the wavelength range of good quantum efficiency of
 644 APDs and VPTs. In the barrel, the crystal front face cross-section is $22 \times 22 \text{ mm}^2$ or
 645 approximately 0.0174×0.0174 in $\eta - \phi$ space. This size is about the Molière radius.
 646 The crystal length is 230 mm corresponding to $25.8 X_0$. Most of the crystal faces are
 647 polished except one lateral face in order to make the light collection uniform. In the
 648 endcap, the crystals have a rear face cross section of $30 \times 30 \text{ mm}^2$, a front face cross

649 section of $28.62 \times 28.62 \text{ mm}^2$ and a length of 220 mm ($24.7 X_0$). Figure 2.8 shows a
 650 barrel and a endcap crystal and attached photodetectors.

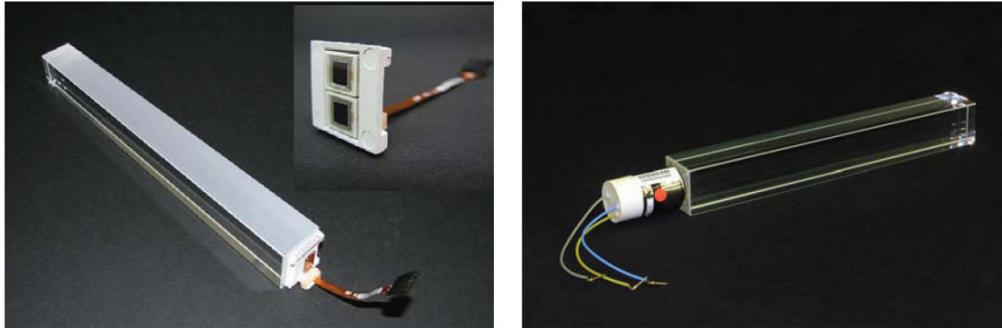

Figure 2.8: ECAL crystals and photodetectors.

651 **The ECAL Photodetectors**

652 The photodetectors are attached to the end of scintillator crystals and convert scin-
 653 tillation light to electronic pulses. The requirements for a photodetector are fast,
 654 radiation tolerant and able to operate in the longitudinal 4 T field. The choices of
 655 photodetector technologies, APD for the barrel and VPT for the endcap, are driven
 656 by the configuration of the magnetic field and the expected level of radiation. VPTs
 657 have lower quantum efficiency and internal gain compared to the APDs. However,
 658 this drawback is compensated by their larger surface coverage on the back face of the
 659 crystals. A pair of APDs is attached to a crystal and each APD has an active area of
 660 $5 \times 5 \text{ mm}^2$. Each VPT has a diameter of 25 mm and an active area of approximately
 661 280 mm^2 . One VPT is glued to the back of each crystal.

662 **Preshower Detector**

663 The main purpose of the preshower is to provide $\pi_0 - \gamma$ separation. At high rapidity,
 664 two photons from π_0 decays are close together and not resolved in ECAL crystals.

665 Therefore, π_0 s are recognized as fake photons and contribute to the backgrounds
 666 in a analysis with photon. A high granularity silicon preshower detector resolves
 667 these two photons; thus the backgrounds from π_0 are reduced. In the Higgs search
 668 in diphotons channel, since about half of the Higgs decays results in one photon in
 669 the ECAL endcap, the fake photon reduction in the ECAL endcap is necessary to
 670 suppress the overall background.

671 The preshower detector is a sampling calorimeter, which is located in front of
 672 the endcap ECAL and covers a fiducial region $1.653 < |\eta| < 2.6$. It consists of two
 673 lead layers to initiate electromagnetic showers from incoming photons or electrons.
 674 A silicon-strip plane with a pitch of 2 mm is placed right after each lead radiator to
 675 measure the deposited energy and the transverse shower profiles. The orientations of
 676 the strips in the two planes are orthogonal. Figure 2.9 shows the layout of preshower
 677 sections. Total material thicknesses before the first and the second silicon sensor
 678 plane are $2 X_0$ and $1 X_0$, respectively. Therefore, about 95% single incident photons
 679 start showering before reaching the second sensor plane. The energy deposited in 2
 680 mm pitch silicon strips is used to determine the impact position of electromagnetic
 681 showers using a charge-weighted-average algorithm. The accuracy is very good,
 682 $\sim 300 \mu\text{m}$ at 50 GeV. This energy measurement is also used in the correction of
 683 energy measured by crystals, which preserves the excellent energy resolution of the
 684 ECAL.

685 Energy resolution

686 The ECAL energy resolution is parametrized as:

$$\left(\frac{\sigma}{E}\right)^2 = \left(\frac{S}{\sqrt{E}}\right)^2 + \left(\frac{N}{E}\right)^2 + C^2 \quad (2.2)$$

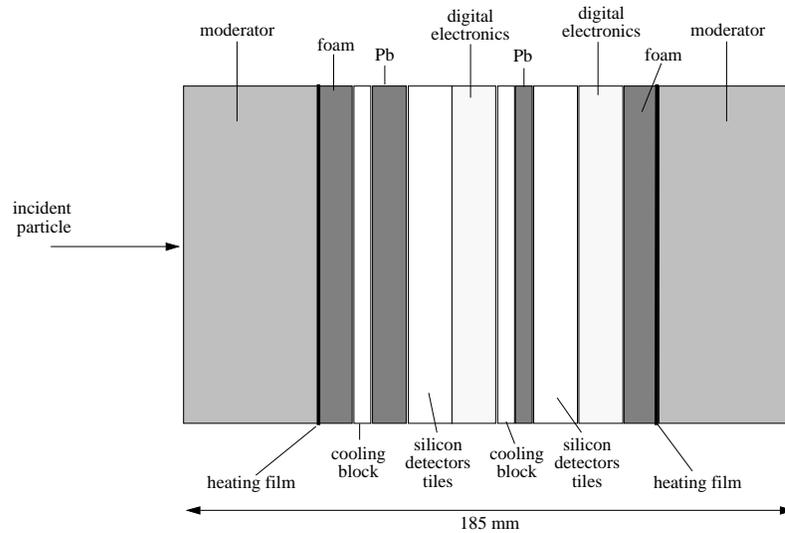

Figure 2.9: Arrangement of the preshower layers.

687 where S is the stochastic term, N is the noise term, and C is the constant term.
 688 This parametrization is valid if the shower leakage from the rear of the calorimeter is
 689 less important (energy is below about 500 GeV). The contribution to S comes from
 690 fluctuations in the lateral shower containment, photostatistics and energy deposit in
 691 the preshower absorber (if present). The electronic, digitization and pileup noises
 692 contribute to the noise term. The constant term is caused by non-uniformity of the
 693 longitudinal light collection, intercalibration errors and leakage of energy from the
 694 back of the crystal.

695 The ECAL energy resolution is measured in the 2004 test beam for electron beam
 696 with momentum between 20 and 250 GeV/ c . The result is showed in Figure 2.10, in
 697 which the stochastic, noise, constant terms are 2.8%, 0.12% and 0.3%, respectively.
 698 For an unconverted photon with shower energy ~ 100 GeV, the constant term dom-
 699 inates. Therefore, the ECAL energy resolution depends strongly on the quality of
 700 the calibration. The particle energy in the ECAL is estimated by [38]:

$$E = F \times \sum_{clustercrystal} G(\text{GeV}/\text{ADC}) \times C_i \times A_i, \quad (2.3)$$

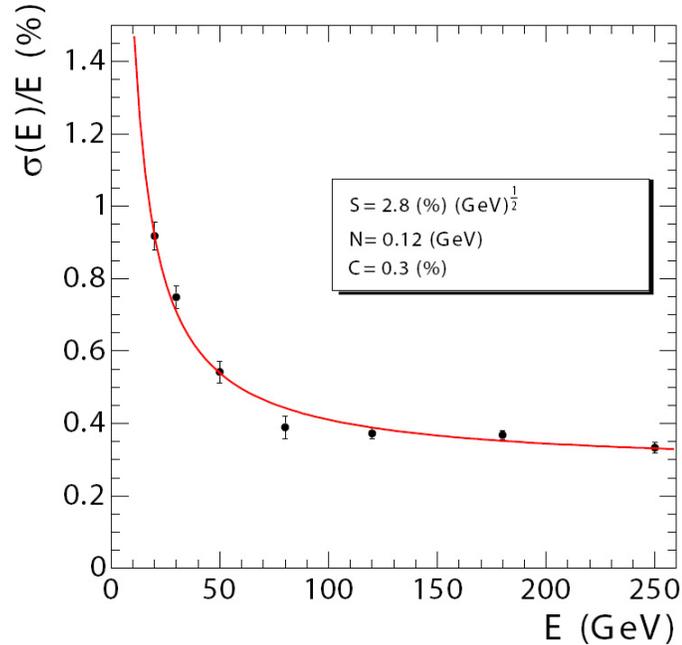

Figure 2.10: ECAL energy resolution.

701 where F is the additional energy correction factor, which depends on particle type,
 702 energy and pseudorapidity. For electron, this factor takes into account for the shower
 703 leakage and the bremsstrahlung losses; G is the ECAL energy scale for ADC to GeV
 704 conversion; A_i are the reconstructed amplitudes in ADC counts; and C_i are the inter-
 705 calibration constants, which come from channel-to-channel variation. Details at the
 706 method to estimate C_i and G using the collision data are discussed in [38].

707 2.2.4 The Hadronic Calorimeter

708 The CMS hadronic calorimeter (HCAL) is a sampling calorimeter made of layers
 709 of dense absorber material and active material. The absorber material is brass or
 710 steel and the active material is scintillator. The hadronic calorimeter is vital for
 711 jets and missing transverse energy measurements. It includes four subsystems: the
 712 Hadronic Barrel (HB), the Hadronic Endcap (HE), the Hadronic Outer (HO) and

713 the Hadronic Forward (HF) calorimeters.

714 The HB covers region $|\eta| < 1.3$ and is placed in the gap between the ECAL outer
 715 extent ($R = 1.77$ m) and the magnet coil inner extent ($R = 2.95$ m). Its thickness is
 716 limited to 5.8 hadronic interaction lengths at $\eta = 0$ and increases to 10 interaction
 717 lengths at $|\eta| = 1.2$ [37]. Therefore, the HO, which is placed outside the solenoid
 718 and covers $|\eta| < 1.26$, is used to catch the energy leakage from HB. The HE covers
 719 region $1.3 < |\eta| < 3.0$ and the HF, placed outside the magnet at $z = 11.2 \pm$ (from
 720 the interaction point to their front faces), covers the forward region $3 < |\eta| < 5.2$.

721 The HF calorimeter uses Cherenkov-based, radiation-hard technology consisting
 722 of quartz fibers and steel. The fibers are parallel to the beam direction. Half of the
 723 fibers are long fibers extending the full length of the HF detector (165 cm), while
 724 other half of the fibers are shorter which stop at a distance of 22 cm from the front
 725 face of the HF. The purpose of this arrangement is to distinguish the electromagnetic
 726 and hadronic showers, since a electromagnetic shower starts to develop earlier than
 727 the hadronic shower and deposits most of its energy in the long fibers while a hadronic
 728 shower starts late and deposits most of its energy in the short fiber.

729 The HB and HO are segmented in towers of 0.087×0.087 in $\eta - \phi$ space. The
 730 HE has the same granularity up to $|\eta| = 1.74$, after that the η segmentation varies
 731 from 0.09 to 0.35 and the ϕ segmentation is 0.175. In the HF, the segmentation is
 732 0.175×0.175 and 0.175×0.35 at $|\eta| < 4.7$ and $|\eta| > 4.7$, respectively [9]. Figure 2.11
 733 shows the segmentation of the HCAL.

734 Light from the scintillation tiles is carried out by the embedded wavelength-
 735 shifting fibers. There are 17 scintillation layers in each HB and HE tower. The
 736 light of all scintillation layers are optically added in the HB. In the HE, the towers

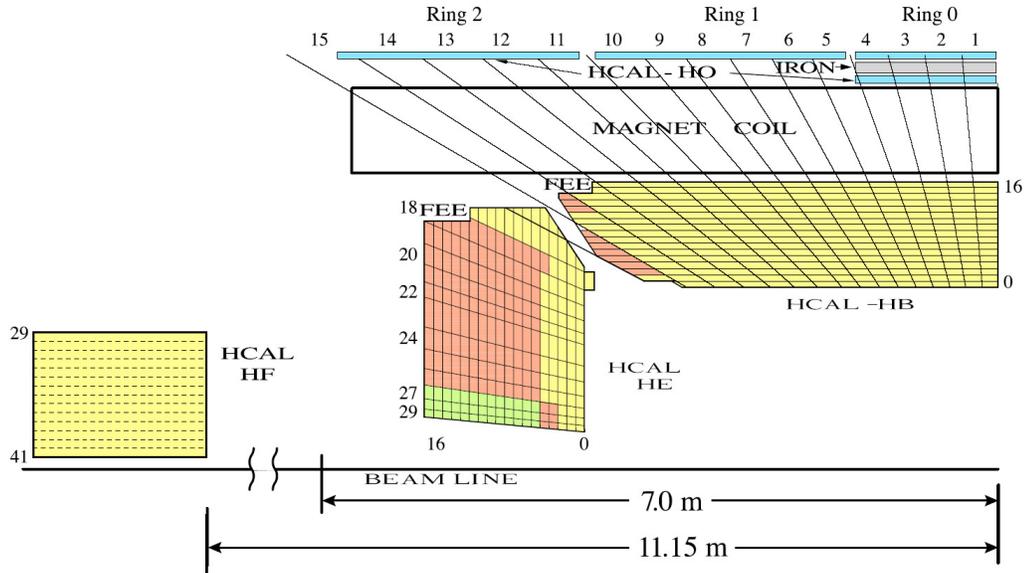

Figure 2.11: The schematic view of the CMS hadronic detector [9].

737 are divided in depths and the light from scintillation layers at the same depth are
 738 added. Finally, light signals are read by hybrid photodetectors (HPD). In the HF,
 739 lights from the fibers are collected by photomultipliers (PMT) housed in the read-out
 740 boxes.

741 2.2.5 The Muon Detector

742 The CMS muon detectors are gaseous detectors used for muon trigger, identification,
 743 charge and momentum measurements. They are composed of 1400 chambers of 3
 744 types: 250 drift tube chambers (DT) in the barrel ($|\eta| < 1.2$), 468 cathode strip
 745 chambers (CSC) in the endcap disks ($1.2 < |\eta| < 2.4$) and 610 resistive plate chambers
 746 (RPC). The RPCs are mounted together with both the DT and CSC. The DT
 747 technology is the choice for the barrel because of small neutron-induced background,
 748 low muon rate and uniform magnetic field (mostly contained in the return yoke) in
 749 this region. In the endcap, the muon rates and background levels are high and the

750 magnetic field is large and non-uniform. Thus, cathode strip chambers (CSC) are
751 used.

752 The DT chambers are installed in hollows of the 5-wheel return yokes and orga-
753 nized in 4 stations. In the first three stations, each DT chamber composes 12 layers
754 of drift tubes arranged in 3 groups of 4. The two of these groups have wires along
755 z used to measure the ϕ coordinate and the other group measures the z coordinate.
756 There are no z measuring layers in the outermost DT station.

757 The CSC system is arranged in 4 stations perpendicular to the beam pipe and
758 mounted on the endcap disks. Each CSC chamber is built from 6 cathode planes
759 and anode wires. In order to measure the position of a muon hit, cathode planes are
760 segmented into narrow trapezoidal strips projecting radially from the beam line and
761 anode wires are aligned perpendicularly to the strips.

762 The RPCs are fast gaseous detectors, which are added to both barrel and endcap
763 (up to $|\eta| < 1.6$). Their purposes are to provide fast, independent, and highly-
764 segmented trigger and help to resolve ambiguities when there are multiple hits in
765 a chamber. In the barrel, 6 layers of RPCs are embedded, 2 in each of the first
766 2 stations, and 1 in each of the last 2 stations. In the endcap region, there is a
767 plane of RPCs in each of the first 3 stations. This arrangement allows the trigger to
768 use the coincidences between stations for reducing backgrounds, improving the time
769 resolution of bunch crossing identification, and for achieving a good p_T resolution.

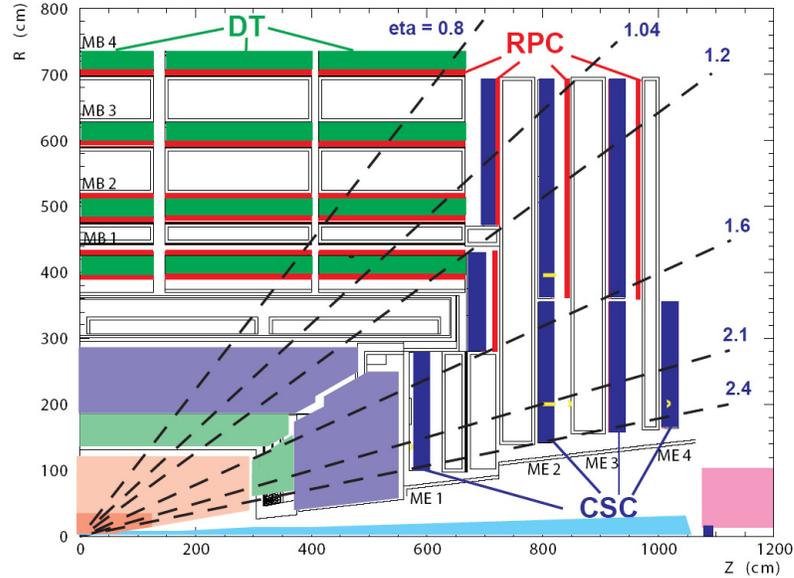

Figure 2.12: The muon detector layout [10].

770 2.2.6 The CMS trigger

771 At the design luminosity, $10^{34} \text{ cm}^{-2} \text{ s}^{-1}$, the LHC crossing rate is 40 MHz with
 772 about 20 pp simultaneous collisions in each crossing. Because of this enormous
 773 rate, it is impossible to store all the events, and a trigger system is used to reduce
 774 dramatically the rate (by a factor 10^6) by selecting just most interesting events
 775 for physics analysis. The CMS trigger is a 2-level architecture trigger. The Level-
 776 1 trigger (L1) is built from fast custom hardware processors with the maximum
 777 bandwidth of 100 kHz (the practical maximum output rate is 30 kHz, assuming an
 778 approximate safety factor of three). The L1 trigger system is divided in 3 subsystems:
 779 the L1 calorimeter trigger, the L1 muon trigger, and the L1 global trigger. The muon
 780 trigger system comprises 3 subsystems corresponding to 3 muon subdetectors, the
 781 Drift Tube Trigger in the barrel, the Cathode Strip Chamber (CSC) trigger in the
 782 endcap and the Resistive Plate Chamber (RPC) covering both barrel and endcap.

783 Trigger information from the DT, CSC and RPC trigger systems is combined at

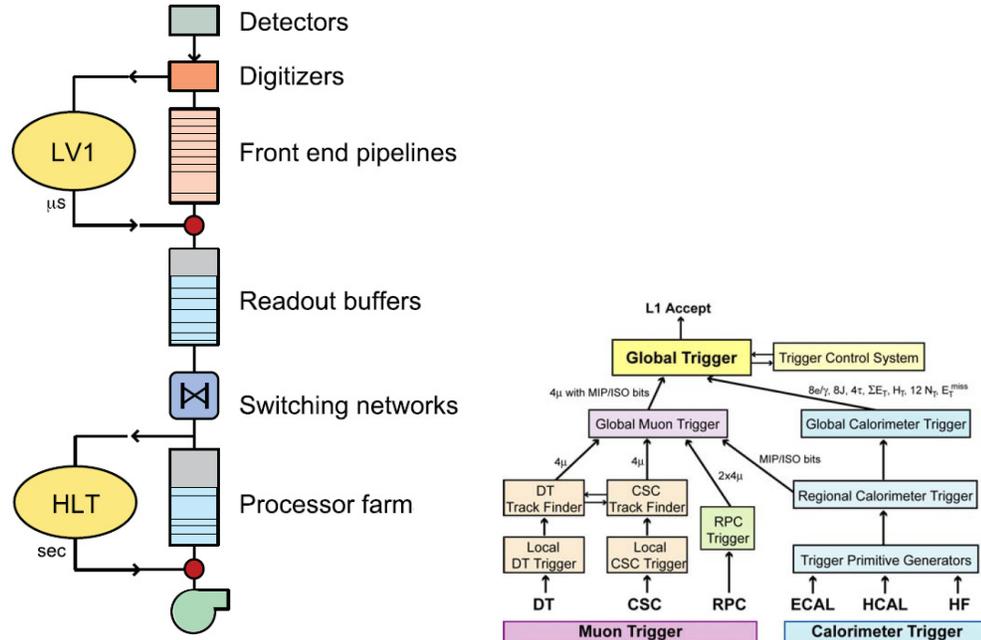

Figure 2.13: The structure of the CMS trigger (left) and the L1 trigger (right) [10].

784 the L1 global muon trigger and sent to the L1 global trigger. Up to 4 candidates from
 785 each of the DT and CSC triggers and up to 8 candidates (4 in the barrel, and 4 in the
 786 endcap) from the RPC trigger are sent to the L1 global muon trigger which in turn
 787 sends 4 highest quality muons to the L1 global trigger. In the calorimeter trigger,
 788 the trigger primitives constructed from the energy sums in the trigger towers of the
 789 ECAL, HCAL and HF are generated by the Trigger Primitive Generator (TPG). The
 790 TPG information is transmitted to the Regional Calorimeter Trigger (RCT), which
 791 combine them together into regions of the size of 4 x 4 towers in the central region
 792 and somewhat larger size in the forward direction. These regions are transferred
 793 to the Global Calorimeter Trigger (GCT). The GCT finds isolated or non-isolated
 794 electron/photon, tau, jet candidates and the sum of transverse energy, performs
 795 the candidate sorting based on their ranks and forwards the top 4 of each type to
 796 the global trigger. The total transverse energy and total missing energy vector are
 797 also calculate by the GCT. Finally, the GCT information is forwarded to the global
 798 trigger, which issues the trigger decision. This trigger decision is transmitted to all of

799 the subdetector front-end and readout systems by the Trigger Timing and Control
800 system. The L1 pipeline data storage time is $3.2 \mu\text{s}$. Therefore, the L1 trigger
801 calculations is limited in many cases in less than $1 \mu\text{s}$ [39].

802 The High-Level Trigger (HLT) is a software system implemented in a filter farm
803 of commercial processors (Event Filter Farm) which reduces further the event rate
804 from L1 trigger to the order of 100 Hz before data storage. The HLT access to
805 complete read-out data via a 100 Gb/s switching network. Thus, it has the capacity
806 to perform sophisticated calculations based on reconstruction algorithms similar to
807 those of the off-line analysis.

808 Chapter 3

809 Event Reconstruction

810 The purpose of this chapter is to overview the reconstruction of objects from signals
811 in sub detectors. These signals are produced when particles from the interaction
812 points transverse through detector materials. Trajectories of charge particles are
813 measured in the tracker (Section 3.1). Measurements of muon tracks use information
814 from both the tracker and the muon chambers (Section 3.3). Electrons and photon
815 are measured in the electromagnetic calorimeter (ECAL) (Section 3.5). The electron
816 track are reconstructed in the tracker. Finally, jets and missing transverse energy
817 are reconstructed from the energy deposits in the calorimeter towers (Section 3.4). A
818 calorimeter tower is a combination of a hadronic (HCAL) tower and electromagnetic
819 crystals located in front of this HCAL tower.

820 **3.1 Track Reconstruction**

821 Tracks are reconstructed by Combinatorial Track Finder (CFT) following these steps:
822 local reconstruction, seed generation, pattern recognition, final track fit and track
823 selection. The track reconstruction in CMS begins with hits reconstructed by local
824 reconstruction in the pixel and strip detector. The seed generation step defines initial
825 trajectory parameters and their uncertainties. At least 3 hits or 2 hits and a beam
826 constraint are required to identify five parameters needed for trajectory building.
827 Reconstructing track seeds from the most inner layer of the tracker is more preferred
828 due to higher density of the read-out channel per square unit and less interaction
829 between particle and material. These conditions ensure precision of the initial track
830 parameter estimation. These are common seeding types used in CMS: pixel triplets,
831 pixel and strip pairs with vertex constraint or with beam-spot constraint, strip-only
832 pairs with beam-spot constraint [40].

833 The pattern recognition is based on the Kalman filter [41]. Beginning with a
834 coarse estimation of track parameters from the track seeding, the filter proceeds
835 from layer to layer to find compatible hits. If a hit is found, it is included in the
836 trajectory and the track parameters are updated with information from this hit.
837 The iteration stops when the outermost layer is reached or no compatible hit is
838 found. This step results in number of track candidates satisfying requirements on
839 normalized χ^2 and number of valid and invalid hits. The final track fit refits the
840 track candidates for a full track information.

841 The track selection step reduces large number of fake tracks. In the current
842 CMS implementation, the CFT iterates for 6 times [42]. After an iteration, the
843 unambiguous track clusters assigned to tracks are removed from the cluster iteration

844 used in the next iteration. The tracks which is likely fake are also rejected. The
 845 remaining tracks are assigned a quality flag based on restriction on normalize χ^2 ,
 846 the longitudinal and transverse impact parameters with respect to the beam-spot,
 847 and their significance. Poorly quality tracks are further rejected and highPurity
 848 flag is assigned for tracks that pass the tightest selection [42]. Figure 3.1 shows the
 impact parameter resolution in 2010 pp collision data.

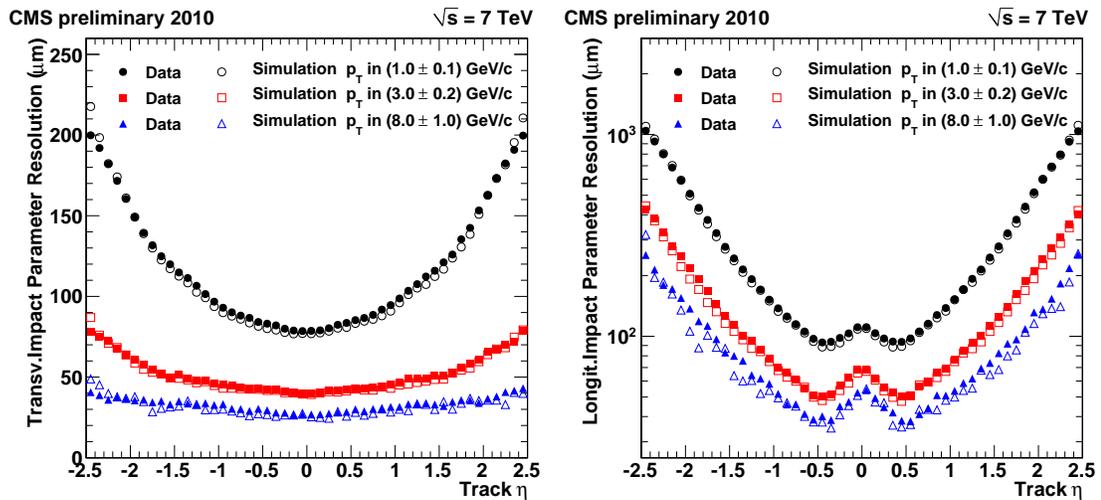

Figure 3.1: The track impact parameter resolutions [11]

849

850 3.2 Vertex Reconstruction

851 The primary vertex reconstruction finds the location of interaction vertex and its
 852 uncertainty. The main idea is to use reconstructed tracks which are close together
 853 when comparing their impact parameters. The tracks are required to originate from
 854 the primary interaction region and satisfy criteria on the transverse impact parameter
 855 significance with respect to the beam line, number of strip and pixel hits, and the
 856 normalized χ^2 . The next step is to form vertex candidates by grouping tracks that
 857 are separated in z_0 , z coordinate of the impact point, by less than $z_0 < 1$ cm compared

858 to their closet neighbor.

859 A vertex fitting is performed by an adaptive vertex fit [43] on vertex candidates
 860 containing at least two tracks. The best estimations of vertex parameters (position
 861 and covariance matrix) are found together with parameters to indicate fit quality,
 862 for example χ^2/n_{dof} and the track weights. Track weights are from 0 to 1 based on
 863 the track compatibility with the common vertex. The reconstruction efficiency is
 864 approximate 100% for primary vertex containing more than 2 tracks with transverse
 865 momenta greater than 0.5 GeV. In the minimum bias data at 7 TeV, the x(y) and
 866 z resolution are close to 25 μm and 20 μm for primary vertex with more than 30
 867 tracks [11].

868 **3.3 Muon reconstruction**

869 Muon track reconstruction combine hits in the tracker and in the muon chambers.
 870 Muon tracks are reconstructed separately in the silicon tracker and muon chambers
 871 (stand-alone muon track). These are merged by outside-in (global muon reconstruc-
 872 tion) or inside-out (tracker muon reconstruction) algorithms. In the global muon
 873 reconstruction, a standalone muon track is matched with a tracker track and the
 874 hits of those tracks are combined in a common fit to find the global muon track.
 875 This method improves the momentum resolutions of high p_T tracks ($p_T \geq 200$ GeV)
 876 compared to tracker-only fit. In the tracker muon approach, tracker tracks with
 877 $p_T > 0.5$ GeV/c and $p > 2.5$ GeV/c are considered as muon candidates and they are
 878 extrapolated to the muon systems to find a match muon segment found from DT
 879 or CSC hits. Energy loss and uncertainty due to multiple scattering are considered
 880 in the extrapolation. If the matching is found, the tracker track is considered as

881 tracker-muon track. Because the method requires only a matched single muon seg-
 882 ment in muon chambers, it has higher reconstruction efficiency for low p_T tracks
 883 compared to the global muon reconstruction.

884 About 1% of muon from collisions fail to be reconstructed by two methods above
 885 but are found by the stand-alone tracker only approach [12]. Finally, muon candi-
 886 dates found by all three algorithms are merged to a single collection. Each candidate
 887 contains available information from the stand-alone, the tracker-track and the global
 888 fit. If two candidates are found by Tracker Muon and Global Muon and share the
 889 same tracker track, they are merged into a single candidate. If a standalone-muon
 890 track shares a muon segment with a tracker muon and is not included in a global
 891 muon track, it is merged to the tracker muon. Figure 3.2 shows the reconstruction
 efficiency of the global muon.

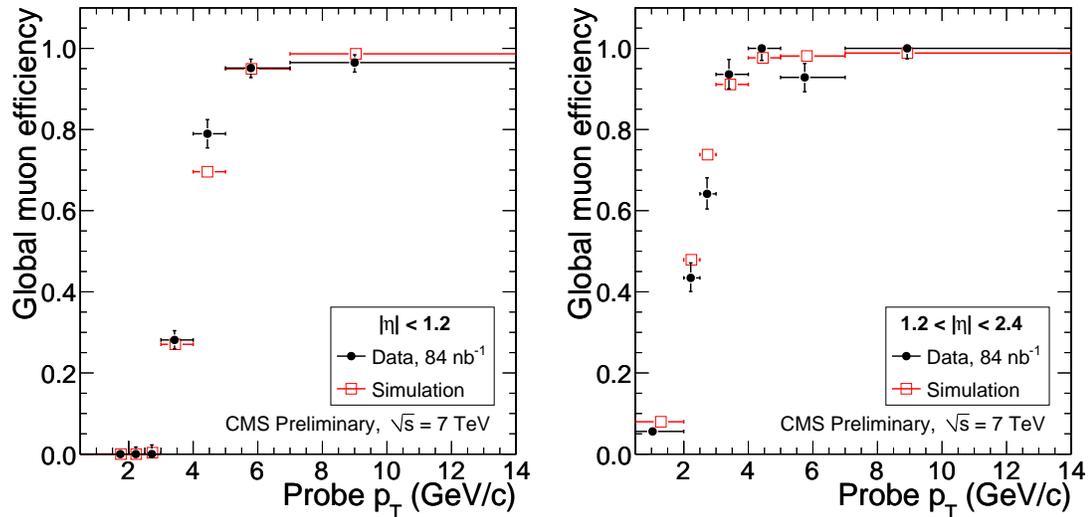

Figure 3.2: Muon reconstruction efficiency [12]

893 3.4 Jet and Missing ET reconstruction

894 The fragmentation of quarks and gluons in the final state results in a stream of
 895 collimated particles. A calorimeter clustering algorithm clusters energy deposit in the
 896 calorimeter tower to form a jet. A calorimeter tower is a combination of HCAL cells
 897 and geometrically corresponding ECAL crystals. One HCAL cell corresponds to 5×5
 898 ECAL crystals in the barrel ($|\eta| < 1.4$). In the endcap, the HCAL-ECAL mapping
 899 is more complex. A successful algorithm should be collinear-safe and infrared-safe [44].
 900 Collinear-safe requires that the outcome remains unchanged if the energy of a original
 901 single particle is distributed among two collinear particles. Infrared-safe means that
 902 the result of the jet finding is stable against addition of soft particles. Below are
 903 some of the algorithms used in CMS:

- 904 • Iterative cone: this is a simple cone-based algorithm which performs iterative
 905 searches for stable cones. Starting from a seed crystal or particle, all inputs
 906 within $\sqrt{\delta\eta^2 + \delta\phi^2} \leq R$ are associated with a jet. R is the cone-size parameter
 907 (popular choice is 0.5). If the cone geometric center agrees with the (η, ϕ)
 908 location of the sum of the constituent four vectors, a jet is found. This algo-
 909 rithm is not collinear-safe and infrared-safe but it is fast and has predictable
 910 calculation time. Thus, it is implemented in the HLT.
- 911 • Midpoint cone [45]: this method uses iterative cone technique to find stable
 912 cones. However, there are two improvements to address the infrared-safe con-
 913 dition. Midpoints between each pair of (proto-)jets, which are closer than
 914 twice the cone radius R , are used as additional seeds and each input can ini-
 915 tially be associated with several protojets. A splitting and merging algorithm
 916 is implemented to ensure that each input appears in one jet only. Despite
 917 these improvements, the algorithm is not infrared-safe for pQCD order beyond

918 NLO [45].

- 919 • k_T algorithm: the clustering is decided by distance quantities assigned for each
- 920 protojet

$$d_i = (E_{T,i}^2)R^2 \quad (3.1)$$

$$d_{ij} = \min(E_{T,i}^2, E_{T,j}^2 R_{ij}^2) \quad (3.2)$$

$$R_{ij}^2 = (\eta_i - \eta_j)^2 + (\phi_i - \phi_j)^2 \quad (3.3)$$

921 where $E_{T,i}$ is the transverse energy of i^{th} protojet, $R_{i,j}^2$ is the distance between
 922 two protojets. R^2 is a dimensionless parameter. The next step is to sort the
 923 list of d_i and d_{ij} and finds the smallest values. If the smallest value is d_i type,
 924 the corresponding protojet is considered as a jet and removed from the list. If
 925 the smallest value is d_{ij} , the protojet pair is recombined. The distances are
 926 recalculated and the whole procedure is repeated. The search stops when the
 927 list is empty. There is an extension to this method called anti- k_T algorithm
 928 which uses these distance definitions [46].

$$d_{iB} = E_{T,i}^{2p} \quad (3.4)$$

$$d_{ij} = \min(E_{T,i}^{2p}, k_{T,j}^{2p}) \frac{R_{ij}^2}{R^2} \quad (3.5)$$

929 p is a parameter to tune the relative power of the energy and geometrical
 930 scales, R_{ij} . For $p=1$, this returns to the normal k_T algorithm and for $p>0$, the
 931 performance is similar to the k_T method. The anti- k_T jet-clustering algorithm
 932 corresponds to $p=-1$.

- 933 • SISCone (Seedless Infrared-Safe Cone) is a jet algorithm which is collinear-
 934 and infrared-safe to all orders of pQCD. The calculation time is slightly higher
 935 compared to the Midpoint Cone algorithm [44].

936 There are four types of jets reconstructed in CMS. The differences between these
 937 are the combination of subdetector information to provide inputs for the jet clus-
 938 tering algorithm. The calorimeter jets are reconstructed from energy deposit in
 939 calorimeter towers by the clustering methods describe above. Utilizing the excellent
 940 momentum reconstruction of the tracker, calorimeter jets are combined with nearby
 941 charged tracks reconstructed in the tracker to form jet-plus-track jets [47]. The p_T
 942 respond and the energy resolution of jets are improved due to better momentum
 943 measurements in the tracker. The particle flow algorithm is used to reconstruct
 944 PFlow jets [48]. A list of all particles reconstructed by all subdetectors is found
 945 and PFlow jets are reconstructed from this list. Finally, track jets are reconstructed
 946 based on well measured tracks in the central tracker [49].

947 Jet energy measured in the detector is corrected for a better measurement of par-
 948 ticle jet energy. CMS adopts factorized multi-step procedure for the jet energy cor-
 949 rection: offset, relative and absolute corrections [50]. The offset correction removes
 950 the unwanted energy due to electronic noise and pile-up. The relative correction
 951 uniforms the jet respond vs jet η with respect to a central control region chosen as
 952 a reference. Finally, the variation of jet respond vs. p_T is removed by the absolute
 953 correction:

$$E_{corr} = (E_{uncorr} - E_{offset}) \times C_{Rel}(\eta, p_T'') \times C_{Abs}(p_T') \quad (3.6)$$

954 where p_T'' is the jet transverse momentum given by offset correction and $p_T' = p_T'' \times$
 955 $C_{Rel}(\eta, p_T'')$ is the transverse momentum given by the offset and relative correction. At
 956 the initial stage of LHC running, the correction is done in MC simulation. It can also
 957 be done using physics processes from the pp collision (dijet and photon+jet balance).
 958 Figure 3.3 shows the total jet energy scale uncertainty in 2010 collision data at 7
 959 TeV. Current CMS analyses use conservative 10% jet energy scale uncertainty for
 960 calorimeter jet and 5% uncertainty for jet-plus-track and PFlow jets with additional

2% per unit of rapidity.

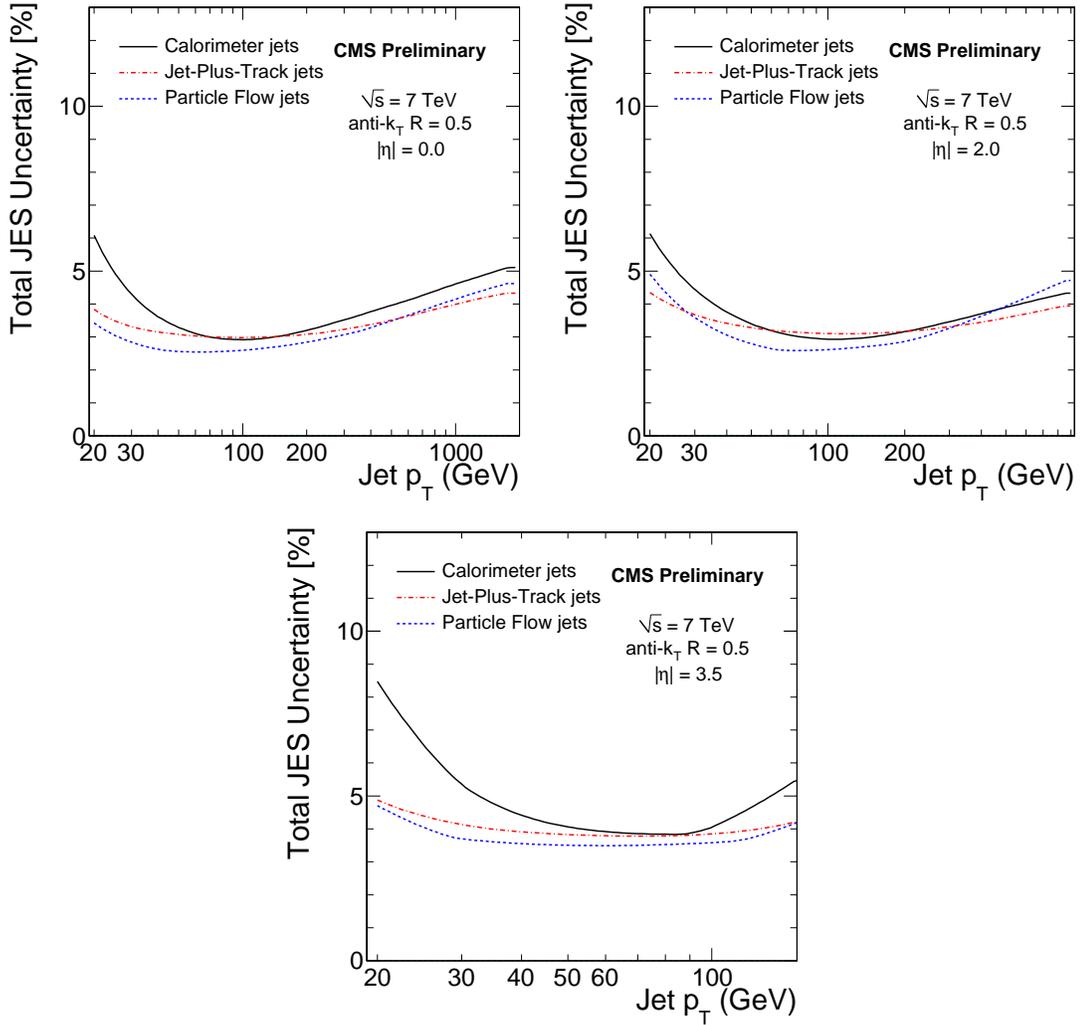

Figure 3.3: Jet energy scale uncertainty [13]

961

962 Weakly interaction particles, for example, neutrinos, transverse the detector with-
 963 out depositing their energy. The missing transverse energy is an indication of the
 964 production of such particles in the pp collision. The missing transverse energy is
 965 defined as [51]:

$$\vec{E}_T = - \sum n (E_n \sin \theta_n \cos \phi_n \vec{i} + E_n \sin \theta_n \sin \phi_n \vec{j}) = E_x \vec{i} + E_y \vec{j} \quad (3.7)$$

966 where n runs over all calorimeter input object, for example, energy deposit in towers
 967 or generated-level particle energy, \vec{i} , \vec{j} are the unit vectors in the direction of the
 968 x and y axes. If there is no missing transverse energy from physics processes, the
 969 \cancel{E}_x and \cancel{E}_y distribute as Gaussians with zero mean and standard deviation σ , while
 970 the magnitude of missing transverse energy vector, \cancel{E}_T , distribution has the shape
 971 described by $\frac{2\pi}{\sigma} \theta(\cancel{E}_T) \times G(\cancel{E}_T, 0, \sigma)$. In this formula, $\theta(\cancel{E}_T)$ is the step function and
 972 G is the Gaussian function. The missing transverse energy resolution is estimated
 973 by the quadrature sum of the noise term A, stochastic term B and constant term
 974 C [51]:

$$\sigma(\cancel{E}_T) = A \oplus B \sqrt{\sum E_T - D} \oplus C(\sum E_T - D), \quad (3.8)$$

975 where $\sum E_T = \sum n E_n \sin \theta_n$ is the Scalar Transverse Energy and D is the offset
 976 caused by the noise effect and pile-up on $\sum E_T$.

977 CMS use three types of \cancel{E}_T : calorimeter-tower based (CaloMET), calorimet-jet
 978 based (MHT) and particle flow based (PFMET) \cancel{E}_T . The CaloMET and MHT are
 979 corrected in sequence for muons, jet energy scale effect, taus, underlying event/pile-
 980 up. Details are described in [51]. Instead of using jet energy scale correction, a
 981 track-base correction, which replaces the calorimeter tower respond for charged par-
 982 ticle momentum measured in the tracker, is applied for CaloMET [52]. The PF
 983 algorithm reconstructs individual particles with high precisions. Thus, the PFMET
 984 is calculated from the charged and neutral particle energy deposit without the need
 985 of a correction. Figure 3.4 shows the missing transverse energy of multijet events in
 986 7 TeV collision data.

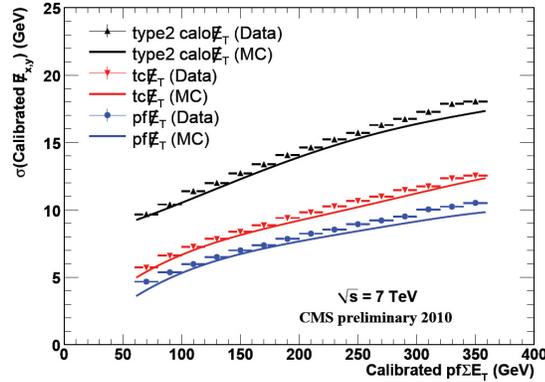

Figure 3.4: Jet energy scale uncertainty [14]

987 3.5 Photon and Electron

988 3.5.1 ECAL clustering

989 The clustering methods used in CMS to reconstruct photon and electron objects are
 990 hybrid and island algorithm [53].

- 991 • Island algorithm: This algorithm forms clusters of crystals containing deposit
 992 energy from a shower around seed crystals. The energy of the seed crystals
 993 are above a certain threshold. The clusters are collected one-by-one while
 994 the search moves in η and ϕ directions. Figure 3.5 illustrates the algorithm.
 995 Starting from the seed crystal position, it moves in both ϕ directions and stops
 996 when there is an increase in energy or a hole (very low energy crystal). The
 997 search in ϕ direction is repeated for each η step and in both η directions. The
 998 algorithm also stops in a η direction if it encounters an increase in energy
 999 or a hole. In order to cover the energy spread due to radiation, clusters are
 1000 clustered in a supercluster in a similar way as forming cluster of crystals. Non
 1001 overlapping clusters around a seed cluster within narrow η window and much
 1002 wider ϕ window are collected in a supercluster.

- 1003 • Hybrid algorithm: The clustering starts from a seed crystal which has max-
 1004 imum energy in the search region and $E_T > E_T^{hybseed}$. Crystals are grouped
 1005 in 1×3 or 1×5 dominoes aligned in η with the seed crystal. If the energy of
 1006 the central crystal is more than E_{wing} , 1×5 dominoes are chosen. The domino
 1007 grouping proceeds in N_{step} from the seed crystal in both directions (see Fig-
 1008 ure 3.5). The next step is to cluster these dominoes in ϕ requiring that a
 1009 distinct cluster has a seed domino with $E > E_{seed}$. Finally, a cluster of clusters
 1010 is found analogous to the super-cluster of island clusters.

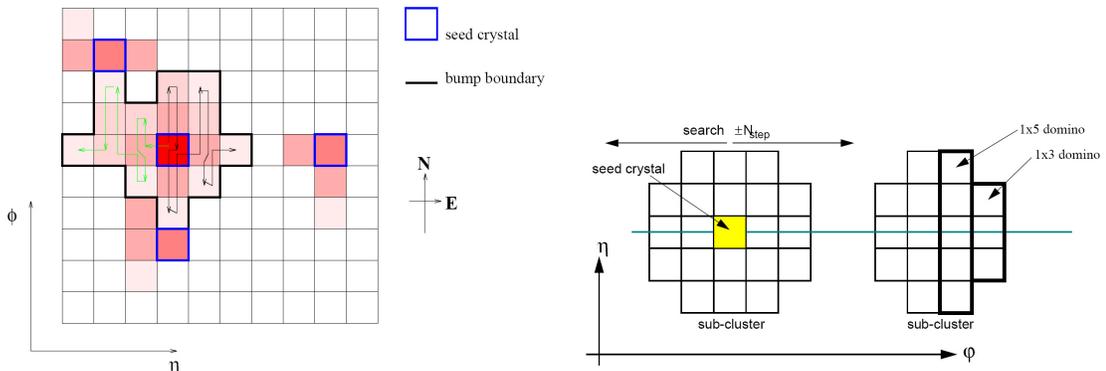

Figure 3.5: Island and hybrid clustering algorithm illustration [?]

1011 3.5.2 Photon candidate

1012 The photon reconstruction starts from summing the photon shower energy deposits
 1013 in the ECAL crystals. An array of 5×5 (3×3) crystals contains 97% (94%) the
 1014 incident energy. Summing the energy measured in such fixed arrays gives the best
 1015 performance for unconverted photons, or for electrons in the test beam [10]. However,
 1016 the presence of the material in front of the ECAL causes the photon conversions and
 1017 the energy deposit spread in ϕ due to the strong magnetic field (the strong magnetic
 1018 field bends the electron and positron tracks, and they radiate in tracker material).
 1019 A cluster of clusters, supercluster, which extends in ϕ , is built to recover fully the

1020 photon energy. The superclusters are reconstructed by the hybrid algorithm, in the
 1021 barrel, or the island algorithm, in the endcaps as described above. A small correction
 1022 (1%) is applied to the supercluster energy in order to compensate for the lateral
 1023 energy leakage due to 3° off-pointing of EB crystal, the interaction with material in
 1024 front of ECAL.

1025 The R9 variable, defined as the ratio of energy contained in a 3×3 array of crystals
 1026 (centred at the crystal with the highest deposited energy) to the supercluster energy,
 1027 indicates the lateral spread of deposit energy. Figure 3.6 shows the R9 variable
 1028 observed in data at 7 TeV. R9 approaches unity for unconverted photons or photons
 1029 which convert very close to the ECAL. This quantity determines which method is
 1030 used for energy calculation. If R9 is above 0.94 (0.95) in the barrel (endcap), the
 1031 photon energy is the energy of the 5×5 crystal array around the seed crystal (the
 1032 highest energy crystal). Below this threshold, the energy of the supercluster is the
 1033 photon energy. In the endcap, the energy deposit in the preshower detector is added
 1034 to the energy of the ECAL clusters. The superclusters or 5×5 clusters are promoted
 to be the photon candidates if the HCAL activity around them is low.

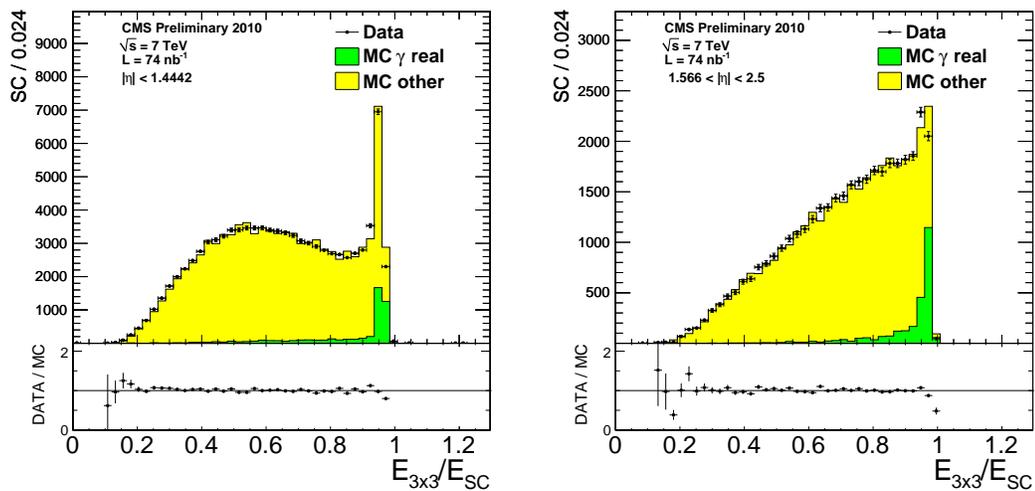

Figure 3.6: R9 distribution [15]

1036 3.5.3 Photon Identification

1037 As described in the previous section, photon objects are reconstructed from corrected
 1038 energy deposition of a supercluster or a 5×5 crystal array. A jet with significant
 1039 fraction of its energy concentrated in neutral π^0 or η causes energy deposit in ECAL.
 1040 Therefore, a fake photon is reconstructed. In order to improve the photon purity, a
 1041 set of identification requirements are applied to photon candidates. These identifi-
 1042 cation requirements are mostly based on the isolation defined as:

- 1043 • *HadronicOverEM*: The hadronic energy divided by the electromagnetic energy
 1044 in the supercluster. The hadronic component is computed as the highest energy
 1045 HCAL `RecHit` within $\Delta R < 0.15$ of the supercluster.
- 1046 • *Tracking Isolation*: Σp_T of tracks within a hollow cone of $0.04 < \Delta R < 0.40$
 1047 about the supercluster.
- 1048 • *ECAL Isolation*: Sum E_T of ECAL `RecHits` within a hollow cone of $0.06 <$
 1049 $\Delta R < 0.40$ about the supercluster. The “Jurassic” footprint, consisting of a
 1050 strip of a specified η width, is removed from the sum.
- 1051 • *HCAL Isolation*: Sum E_T of HCAL `RecHits` within a hollow cone of $0.15 <$
 1052 $\Delta R < 0.40$ about the supercluster.

1053 Showers from photons expand in a few crystals from the seed crystal. The weighted
 1054 width in η of the shower is used as an identification variable.

$$\sigma_{in\eta}^2 = \frac{\sum_i^{5 \times 5} w_i (i\eta_i - i\eta_{seed})^2}{\sum_i^{5 \times 5} w_i}, w_i = \max(0, 0.47 + \ln \frac{E_i}{E_{5 \times 5}}) \quad (3.9)$$

1055 Photons weakly interact with the pixel detector. Therefore, there is no seed in the
 1056 pixel detector associated with photons. Vetoing on present of a pixel seed is an
 optional requirement to distinguish between photons and electrons.

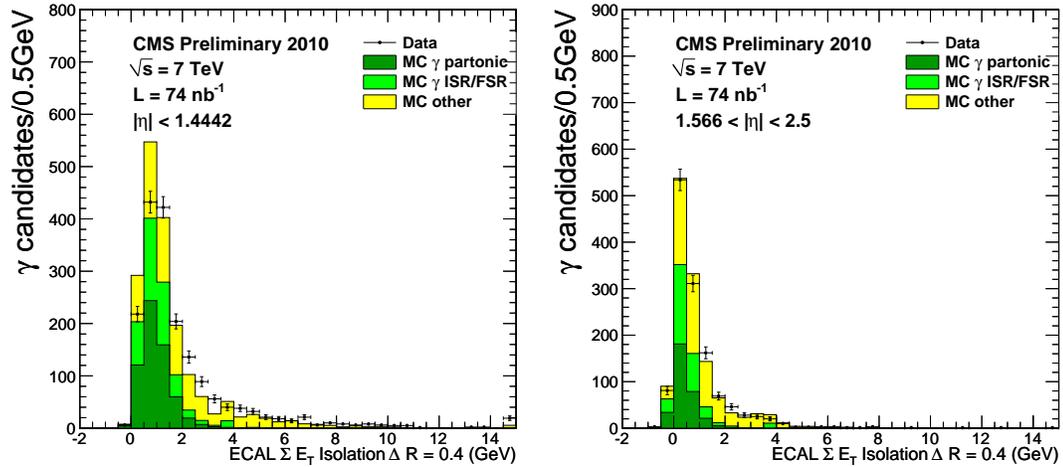

Figure 3.7: ECAL isolation [15]

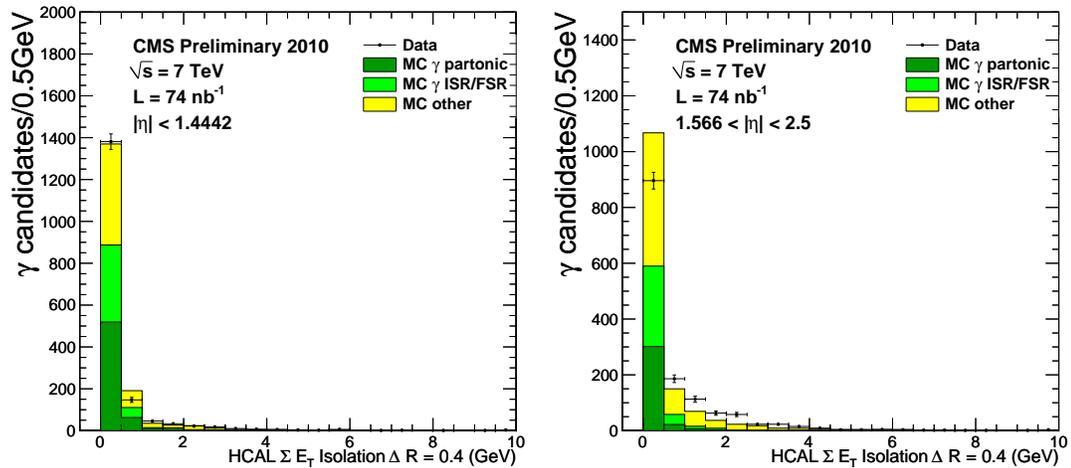

Figure 3.8: HCAL isolation [15]

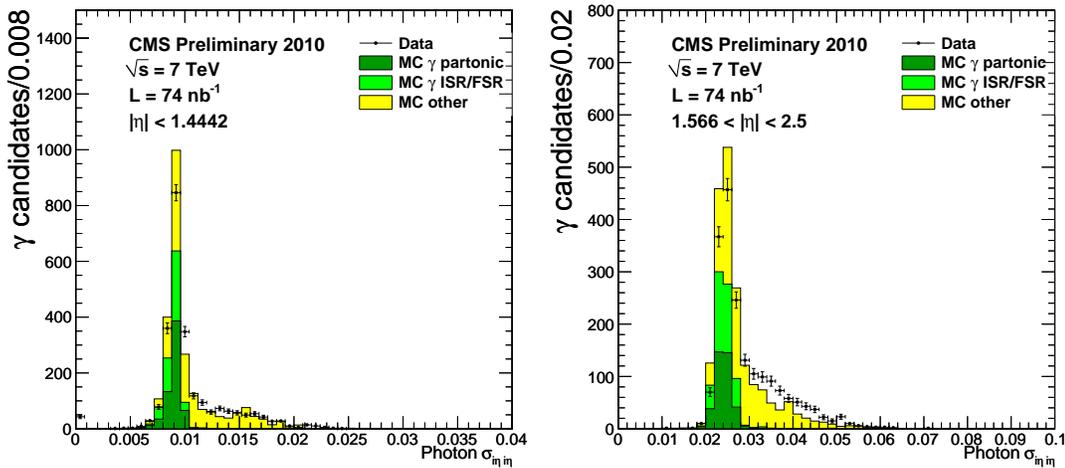

Figure 3.10: Shower shape distribution [15]

1058 3.5.4 Photon conversion

1059 The amount of material (mostly the tracker) in front of the ECAL is about one
 1060 radiation length. Thus, a large fraction of photons is converted before reaching the
 1061 ECAL. Identifying photon conversions benefits the search for $H \rightarrow \gamma\gamma$ in the mass
 1062 range $110 \leq M_H \leq 150 \text{ GeV}/c^2$. This identification improves the poor ECAL energy
 1063 resolution due to conversions and helps reduce the leading π^0 in jets which constitutes

1064 the main irreducible background for the $H \rightarrow \gamma\gamma$ channel [54].

1065 Photon conversions are identified by a pair of an electron and a positron having a
1066 conversion vertex (or their closet approach distance is short). The reconstruction of
1067 e^+e^- track pairs from conversions combines calorimetric and tracking information.
1068 The CMS standard tracking reconstruction are optimized for tracks coming from
1069 the primary interaction vertex with pattern recognition starting from seeds found
1070 in the pixel detector. This method is not suitable for reconstructing the conversion
1071 tracks which originate from conversion points displaced largely from the primary
1072 interaction vertex. A new tracking technique is developed [54]. In this approach, at
1073 first, a predicted track path is found from the ECAL energy deposits (basic cluster)
1074 and the origin of the CMS reference frame. Pairs of hits are sought in the two
1075 outermost layers of the tracker in a small window from the hypothesis tracks. The
1076 search is extended to the third layer if no hit is found in the two outermost layers. If
1077 a compatible hit exists in these layers, the predicted track state is updated, taking
1078 this hit as the starting point. The search continues moving inward to the next layer
1079 until another hit is found. Using pattern recognition and trajectory building, seed
1080 tracks are formed from these pairs of hits. The initial seeds are transformed into
1081 a set of trajectory candidates (limited to 5 in order to avoid large combinatorics).
1082 The result of the inward tracking step is a list of tracks and only the opposite-charge
1083 pair with largest number of reconstructed hits are kept for the next step, outward
1084 tracking. In this step, these tracks are used for the outward seed and track finding
1085 procedure. The tracks are built again from their innermost hit, assumed to be e^+e^-
1086 pair crossing point, and the ECAL basic cluster positions.

1087 Since a photon conversion features a pair of oppositely charged tracks originating
1088 from the same point where the conversion happens (called conversion vertex). Thus,
1089 the angular separations between two tracks at the conversion vertex in the trans-

1090 verse plane ($\delta\phi$) and longitudinal plane ($\delta\cot\theta$) are used for conversion identification.
 1091 Requirement on χ^2 of the vertex fit is needed to ensure the quality of the conversion
 1092 finding. Figure 3.11 shows these variables in the 7 TeV data.

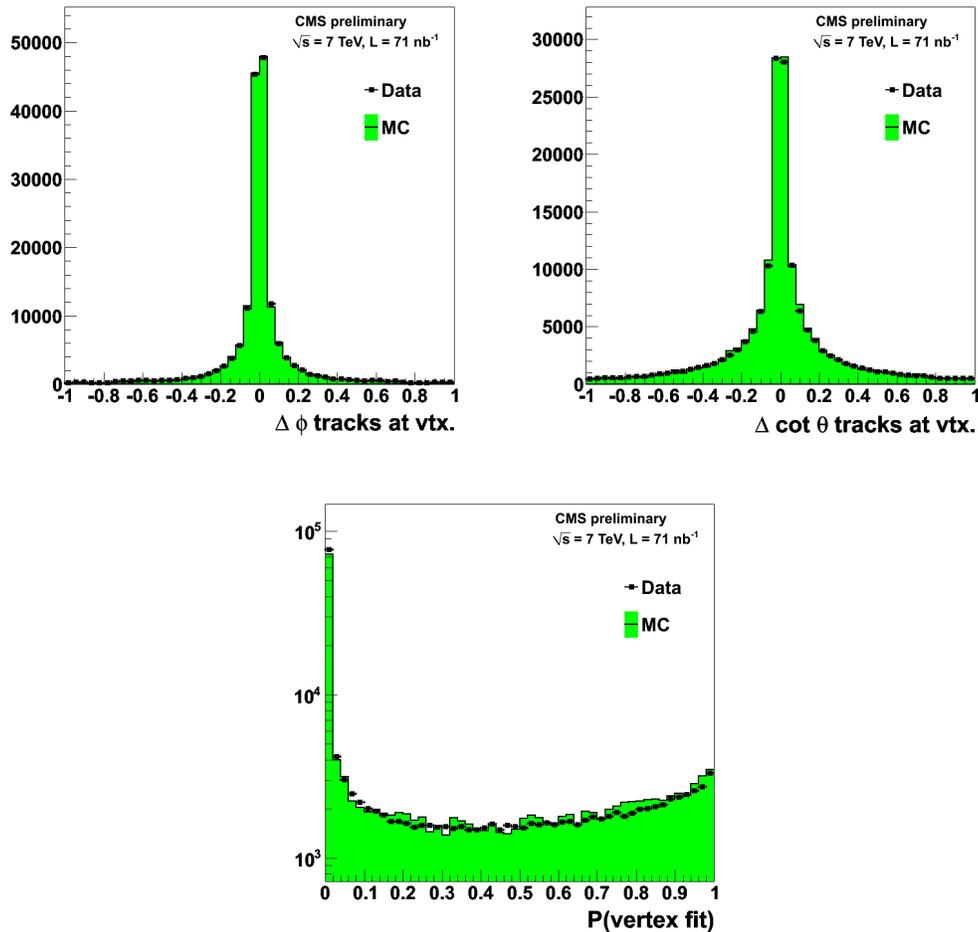

Figure 3.11: Conversion identification variables [15]

1093 3.5.5 Electron

1094 An electron candidate is a supercluster matched with a track. In contrast to photons,
 1095 energy of electrons are measured in supercluster in order to recover bremsstrahlung
 1096 energy lost. Two complement tracking algorithms in the track seeding generation are

1097 used ECAL driven [55] and tracker driven. The ECAL driven methods is optimized
 1098 for an isolated electron with p_T in the range of electron from Z and W decays and
 1099 down to ~ 5 GeV. The tracker driven method performs better for low p_T electrons
 1100 and electrons inside jets. The track reconstruction uses Gaussian sum filter (GSF)
 1101 algorithm which is optimized for electron tracks with long non Gaussian tail in the
 1102 energy loss distribution [56]. The GSF algorithm is built on a specific modeling of
 1103 the electron energy loss and fitted (weighted sum of Gaussian distributions). Thus,
 1104 it can adapt the change of curvature of the electron tracks and measures the track
 1105 momentum at both track ends without a bias. Electrons are classified in the following
 1106 classes [55]:

- 1107 • "golden": a collection of low bremsstrahlung electrons with a reconstructed
 1108 track well matching a supercluster
 - 1109 – a supercluster formed by a single cluster (i.e. without observed bremsstrahlung
 1110 sub-cluster)
 - 1111 – $E/p > 0.9$
 - 1112 – $f_{brem} < 0.5$
- 1113 • "big brem": electrons with high bremsstrahlung fraction but no evidence of
 1114 energy loss effects:
 - 1115 – a supercluster formed by a single cluster,
 - 1116 – $E/p > 0.9$
 - 1117 – $f_{brem} > 0.5$
- 1118 • "showering", or electrons with energy pattern highly affected by bremsstrahlung
 1119 losses:

1120 – a supercluster formed by a single cluster not falling into the "golden" or
 1121 "big brem" classes, or a supercluster formed by several subclusters.

1122 $f_{brem} = (p_{in} - p_{out})/p_{in}$ where p_{in} and p_{out} are the track momenta at the inner-
 1123 most and outermost points. Furthermore, there are "crack" electrons which have
 1124 supercluster's starting crystal close to an η boundary between ECAL modules, or
 1125 between ECAL barrel and endcaps. The classification is used to improve electron
 1126 momentum measurement. For a cut-based analysis, different cuts are designed for
 1127 each electron class. The electron selection can be mostly based on a matching be-
 1128 tween a track and a supercluster, ratios between electron energy and momentum at
 1129 innermost or outermost point of track. Shower shape and isolation variables are also
 1130 used. Figure 3.12 shows the p_T and η distribution in minimum bias events at 7 TeV.

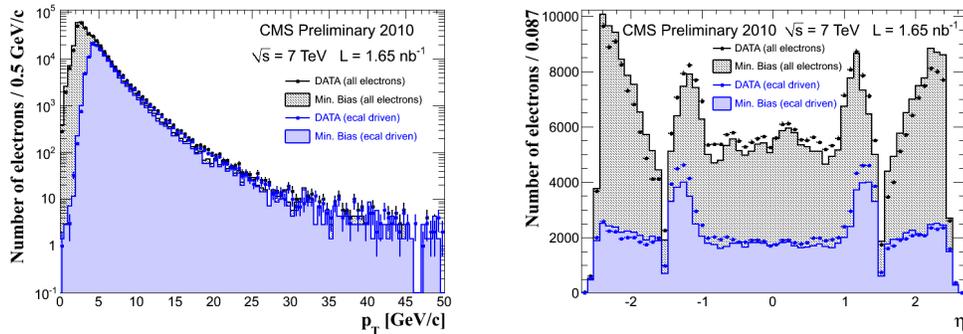

Figure 3.12: p_T and η distribution of electron [16]

1132 Chapter 4

1133 Analysis

1134 The search for large extra dimensions in the diphoton channel are described in this
1135 chapter. We measure the invariant mass spectrum of photon pairs in data and look
1136 for an excess over the SM predictions (backgrounds) at high masses due to the pro-
1137 duction of gravitons decaying to two photons. The high mass region is called the
1138 signal region since the LED signatures, if they exist, present in this region. The
1139 main sources of backgrounds come from the SM diphoton, photon+jet and dijet
1140 processes. From the background studies at the signal region, the SM diphoton back-
1141 ground is the most dominant background followed by the photon+jet background.
1142 The dijet process contributes a smallest fraction of the total background. The SM
1143 diphoton background is estimated in Monte Carlo simulation while photon+jet and
1144 dijet backgrounds are measured by data-driven methods.

1145 This chapter starts with the description of the data and samples used in this
1146 analysis in Section 4.1. Next, we discuss about the optimization of kinematic cuts to
1147 obtain the best sensitivity for the LED signals in Section 4.2. The event selection, its

1148 efficiency and the corresponding jet-faking-photon rate are described in Section 4.3,
1149 Section 4.5 and Section 4.6, respectively. Finally, the method of background estima-
1150 tion are discussed in Section 4.7.

1151 4.1 Data and Monte Carlo Samples

1152 About 36 pb^{-1} of data collected in 2010 runs are used in this analysis. The re-
1153 construction software is updated regularly during the data collection for latest im-
1154 provement and up-to-date running conditions. After the period of data taking (often
1155 between technical stop of the LHC), collected data are reprocessed in order to bring
1156 them to the same reconstruction release which is the latest and greatest. The data
1157 quality is guaranteed by applying a data certification file in the JSON format (Java
1158 Script Object Notation) on top of the data processing. A JSON file includes only
1159 good luminosity sections, where the LHC machine and the CMS detector are in good
1160 operation, giving high quality collision data. The following data sets are used:

- 1161 • EG (Egamma) data set: `/EG/Run2010A-Nov4ReReco_v1/RECO`; lumi: 3.18 pb^{-1} ,
1162 run range: 136035-144114
- 1163 • Photon data set: `/Photon/Run2010B-Nov4ReReco_v1/RECO`; lumi: 32.96 pb^{-1} ,
1164 run range: 146428-149294

1165 These data set are first collected in two data taking periods, Run2010A and
1166 Run2010B. After that they are reprocessed in `CMSSW_3_8_6` release in November,
1167 2010. The EG data set comes from the HLT paths triggering on high transverse
1168 momentum electromagnetic objects (supperclusters). In Run2010B, the luminosity

1169 is increased significantly, the photon data set are selected by tighter HLT photon
 1170 filters to enrich well-defined photon candidates while the rate is maintained.

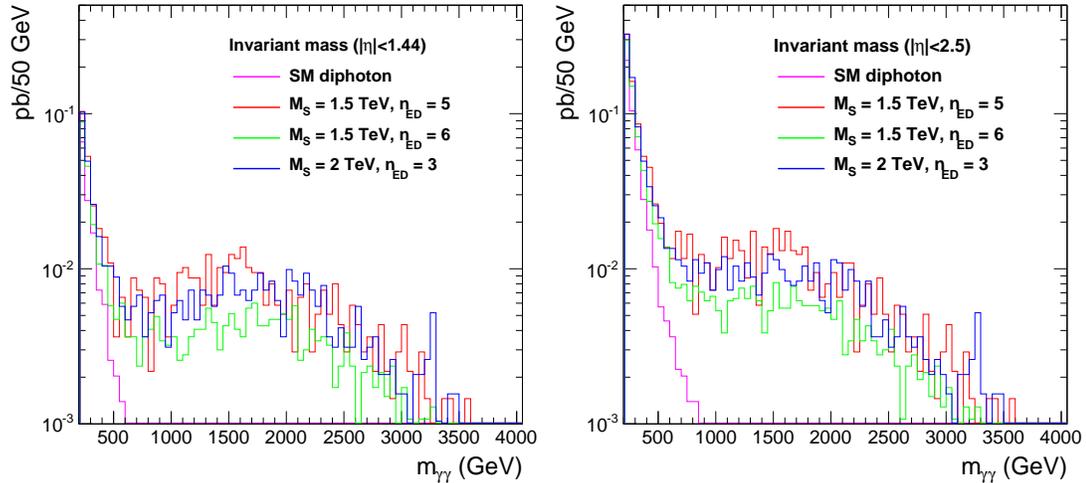

Figure 4.1: Invariant mass distributions of the SM diphotons and some ADD signals. The invariant masses are plotted for EB (left) and EB+EE (right) regions

1170

1171 The general purpose generator PYTHIA [57] is used to generate samples for SM
 1172 diphoton study. PYTHIA contains a library of hard processes and models for initial-
 1173 and nal-state parton showers, multiple parton-parton interactions, beam remnants,
 1174 string fragmentation and particle decays [58]. Both Born and Box process are in-
 1175 cluded in the sample generation. In order to increase the statistic at high \hat{p}_T phase
 1176 space, where \hat{p}_T is the transverse momentum of the hard scattering, the event gener-
 1177 ation is done in separate sub \hat{p}_T phase spaces. Below are the Born and Box samples
 1178 generated in different sub \hat{p}_T phase spaces from 10 to infinity. The σ stands for the
 1179 cross section.

- 1180 • /DiPhotonBorn_Pt10to25/Summer10-START36_V9_S09-v1/GEN-SIM-RECODEBUG,

1202 We use the SHERPA generator version 1.1.2 to generate the ADD signal samples.
1203 *SHERPA* implements the ADD model based on the helicity formalism of spin-2
1204 particles [59]. In order to take into account for the interference between SM diphoton
1205 production and ED diphoton effects, Sherpa generates both processes together. We

1206 generate several signal samples with various values of n_{ED} and M_S . The cross
 1207 sections of the pure ED effect after subtracting the SM term are also shown in
 1208 Table 4.1. We also generate a sample with $M_S = 100$ TeV, which effectively turns
 off virtual graviton effects, while retaining SM diphoton production.

| Sample | Positive Interference (HLZ) | | Negative Interference (Hewett) | |
|-------------------------------|-----------------------------|----------------------------------|--------------------------------|----------------------------------|
| | σ (pb) | $\sigma \times \mathcal{A}$ (pb) | σ (pb) | $\sigma \times \mathcal{A}$ (pb) |
| $M_S = 1.2$ TeV, $n_{ED} = 5$ | 7.31 | 3.19 | — | — |
| $M_S = 1.5$ TeV, $n_{ED} = 2$ | 3.32 | 7.14×10^{-1} | | |
| $M_S = 1.5$ TeV, $n_{ED} = 5$ | 2.16 | 3.34×10^{-1} | 1.90 | 3.04×10^{-1} |
| $M_S = 1.5$ TeV, $n_{ED} = 6$ | 1.69 | 1.82×10^{-1} | | |
| $M_S = 1.5$ TeV, $n_{ED} = 7$ | 1.47 | 1.02×10^{-1} | | |

Table 4.1: Total cross section and cross section \times acceptance for different samples. Cross sections include SM diphoton production in addition to ADD phenomena. The acceptance criteria are two generator-level photons with $E_T > 30$ GeV and $|\eta| < 1.442$ that form an invariant mass $M_{\gamma\gamma} > 500$ GeV. The first set of cross sections (columns two and three) have positive interference between SM and ADD signals, while the second set (columns four and five) have negative interference. The second set is used in the Hewett convention of virtual graviton production. No NLO K -factor is applied.

1209

1210 4.2 Signal Optimization

1211 We optimize our selection criteria to minimize the expected 95% confidence level
 1212 limit on the cross section for the ADD model with parameters close to the expected
 1213 sensitivity. The process of calculating the expected limit is described in detail in
 1214 Section 5.3. For the optimization, we ignore any systematic uncertainties. We opti-

1215 mize based on an estimation of the diphoton rate from MC and the jet background
 1216 from data.

1217 We optimize on two variables: the invariant mass of the photon pairs, and the
 1218 maximum allowed $|\eta|$ of the individual photons. Virtual KK graviton production
 1219 will evince itself as a continuum spectrum above the expected SM background at high
 1220 invariant mass. The signal is also more central than the SM (see Figure 4.2). To
 1221 find the best choice of selection values, we first fix the invariant mass requirement
 1222 at $M_{\gamma\gamma} > 400$ GeV, and then find the optimal $|\eta|$ requirement. Once this is found,
 1223 we fix the $|\eta|$ requirement, and measure the optimal $M_{\gamma\gamma}$ cut. This iterative process
 1224 helps us converge on an optimal point without needing to optimize on both variables
 simultaneously.

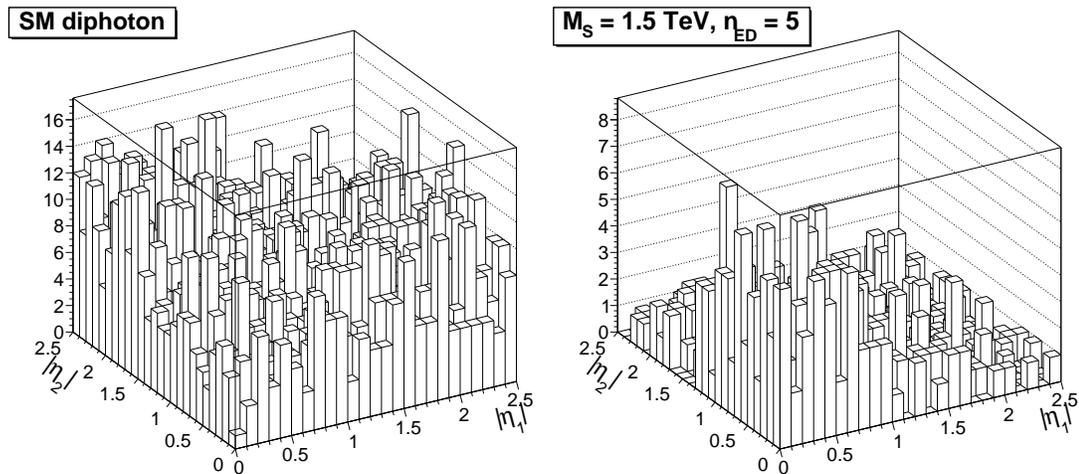

Figure 4.2: Pseudo rapidity distributions of two photons for SM diphoton (left) and ADD signals with $M_S = 1.5$ TeV $n_{ED} = 5$

1225

1226 Figure 4.3 shows both steps of optimization process. The plot on the left is the
 1227 expected 95% confidence level limit on the signal cross section as a function of $|\eta|$
 1228 with $M_{\gamma\gamma} > 400$ GeV for a variety of choices for M_S and the number of ED. The
 1229 normalization is arbitrary since we are looking only for local minima. We choose

1230 $|\eta| < 1.442$, since this conveniently corresponds to both the approximate location
 1231 of the optimal cut point and the location of the gap between the ECAL barrel and
 1232 endcap.

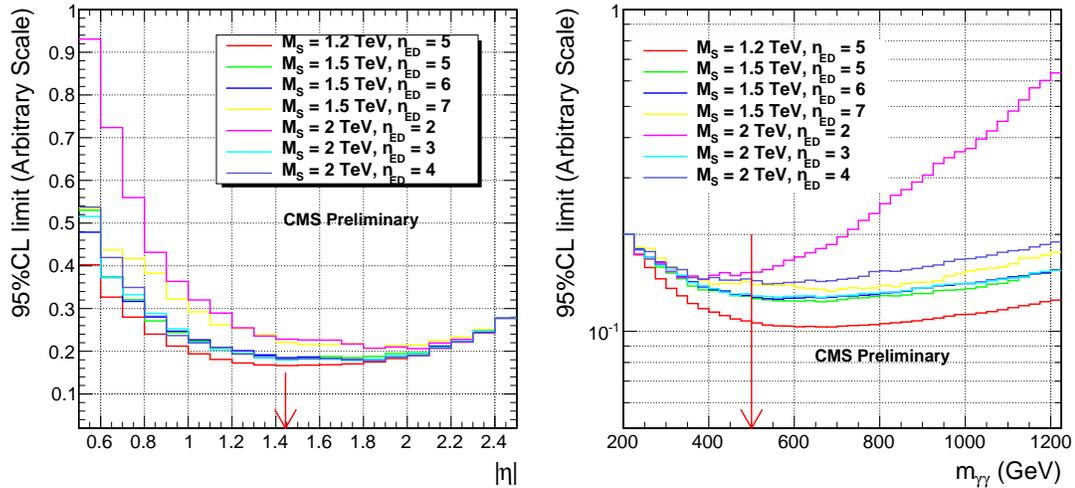

Figure 4.3: Expected 95% limit on the cross section for various ED models. Left: the limit as a function of $|\eta|$ with $M_{\gamma\gamma} > 600$ GeV. Right: the limit as a function of $M_{\gamma\gamma}$ with $|\eta| < 1.442$.

1233 After the optimum $|\eta|$ cut has been chosen, we focus on the invariant mass
 1234 threshold. This is shown in the right pane in Figure 4.3. Based on this plot, we
 1235 choose to require $M_{\gamma\gamma} > 500$ GeV, as this is the optimal point for much of the
 1236 parameter space.

1237 4.3 Event Selection

1238 The final goal of the event selection is to select a high-purity diphoton candidate sam-
 1239 ple without losing hypothetical new physics signals. At first, the events are selected
 1240 by the CMS 2-level trigger systems described in Section 2.2.6. The generic double-
 1241 photon trigger paths in Table 4.2 are used. At least one good vertex within $|z| < 24$
 1242 cm and $d_0 < 2$ cm of the detector center is required, where z is the z -coordinate of

1243 the vertex and d_0 is the distance from the vertex to the beam line. The next step is to
 1244 select events containing two high-transverse-momentum photons. Table 4.3 lists the
 1245 kinematic and the photon identification cuts. The η cut is equivalent to restricting
 1246 two photons to the ECAL barrel. As discussed in Section 4.2, this choice is a good
 1247 compromise between the search sensitivity and the need to understand complicated
 backgrounds in the ECAL endcap.

| Run range | Trigger name | Threshold (GeV) |
|---------------|----------------------------------|-----------------|
| 136033-141881 | <i>HLT_DoublePhoton10_L1R</i> | 10 |
| 141882-144114 | <i>HLT_DoublePhoton15_L1R</i> | 15 |
| 144115-148058 | <i>HLT_DoublePhoton17_L1R</i> | 17 |
| 148059-149294 | <i>HLT_DoublePhoton22_L1R_v1</i> | 22 |

Table 4.2: HLT trigger path

1248

| Cuts | Tight value |
|------------------------|--------------------------------|
| E_T | < 30 GeV |
| $ \eta $ | < 1.4442 |
| EcalIso | $< 4.2 + 0.006 \cdot p_T$ GeV |
| HcalIso | $< 2.2 + 0.0025 \cdot p_T$ GeV |
| TrkIso | $< 2 + 0.001 \cdot p_T$ GeV |
| Pixel seed veto | false |
| $\sigma_{i\eta i\eta}$ | 0.013 |

Table 4.3: Photon selection. The η cut is defined from the sensitivity optimization presented in Section 4.2

1249 4.4 Anomalous energy deposit cleaning

1250 Anomalous energy deposits are isolated high energy deposits observed in ECAL
 1251 barrel due to direct ionization of the avalanche photodiode (APD) sensitive volumes
 1252 by highly ionizing particles, mainly protons and heavy ions, produced during proton-
 1253 proton collisions [17]. Because, these energy deposits are often observed in a single
 1254 ECAL crystal, they are called "spikes". They are found at the rate of ~ 1 in 10^3

1255 minimum bias events. This rate is scaled with \sqrt{s} consistence with the increase in
1256 charged particle multiplicity.

1257 The rejection of those spikes are based on the topological and timing character-
1258 istic. A spike appear as a high energy deposit in a single crystal surrounded by quiet
1259 adjacent crystals. The "Swiss Cross" variable (S) defined as $1 - E_4/E_1$, where E_1 is
1260 the energy of the seed crystal (a crystal with highest energy in a cluster of a photon)
1261 and E_4 is the total energy of four crystal adjacent to the seed crystal, are used in
1262 spike cleaning. A cut at $S < 0.95$ reject 99.2% spikes with $E_T > 10$ GeV [17].

1263 A genuine signal pulse from a photon is the convolution of the time profile of
1264 light emission from the lead tungstate crystals (80% of light emitted in 25 ns) and
1265 the response of the front-end electronics (shaping time $\tau \sim 40$ ns). In contrast, the
1266 signal pulse from a spike contains only the electronic shaping time since the spike
1267 energy deposit happens inside the APD. This difference in shape produces a bias
1268 in the measured time of the signal pulse when the anomalous energy deposits are
1269 reconstructed with the expected pulse shape for scintillation light [17]. A pulse is
1270 declared out-of-time if the difference between the measured and expected time is
1271 greater than 5 standard deviations [17].

1272 Figure 4.4 shows the Swiss Cross variable and the signal timing distributions of
1273 photon. A pronounced peak ~ 1 is seen in Swiss Cross variable distribution for data.
1274 The timing distribution shows many out-of-time photons. Both the Swiss Cross cut
1275 and the timing cut are applied when processing data to reject automatically spike
1276 photons.

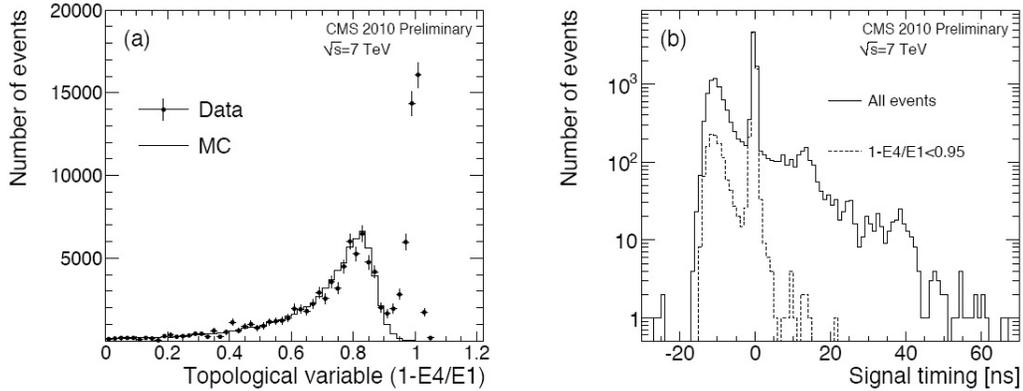

Figure 4.4: (a) Distribution of the Swiss Cross topological variable $(1-E_4/E_1)$ for the highest energy deposit each event for data and simulation ($\sqrt{s} = 7$ TeV); (b) Reconstructed time corresponding to the maximum of the signal pulse for the highest energy deposit in each event [17]

1277 4.5 Photon efficiency

1278 The photon efficiency is measured using the MC photon+jet samples. A generator-
 1279 level photon is spatially matched to a reconstructed photon. If a reconstructed
 1280 photon is found, the photon identification efficiency is calculated. The MC matching
 1281 is necessarily since a photon can be reconstructed from a electromagnetic fluctuation
 1282 of a jet. Figure 4.5 shows the efficiency versus photon p_T and η in MC. The combined
 1283 efficiency is flat in p_T and η and central at 90%. A 2% systematic uncertainty is
 1284 assigned to account for a small variation of the efficiency. In order to correct for the
 1285 difference between efficiency in MC and data, a scale factor is derived. Because of
 1286 the similarity between photons and electrons, this scale factor for photons is similar
 1287 to that of electron which is derived in $Z \rightarrow e^+e^-$ events using the tag-and-probe
 1288 technique. The scale factor value is 1.010 ± 0.012 with the uncertainty covering the
 1289 difference between photons and electrons [60].

1290 Another piece of the photon efficiency is the efficiency of the pixel seed veto which
 1291 is $96.6 \pm 0.5(\text{sys})\%$. This quantity is also estimated in MC and its uncertainty is
 1292 obtained by comparing different geometry configurations of the beam pipe and the

1293 pixel detector [61]. The total single photon efficiency for the selection in Table 4.3 is
 1294 $(87.8 \pm 2.3)\%$ which can be turned into the diphoton reconstruction and identification
 efficiency of $(77.1 \pm 4.5)\%$.

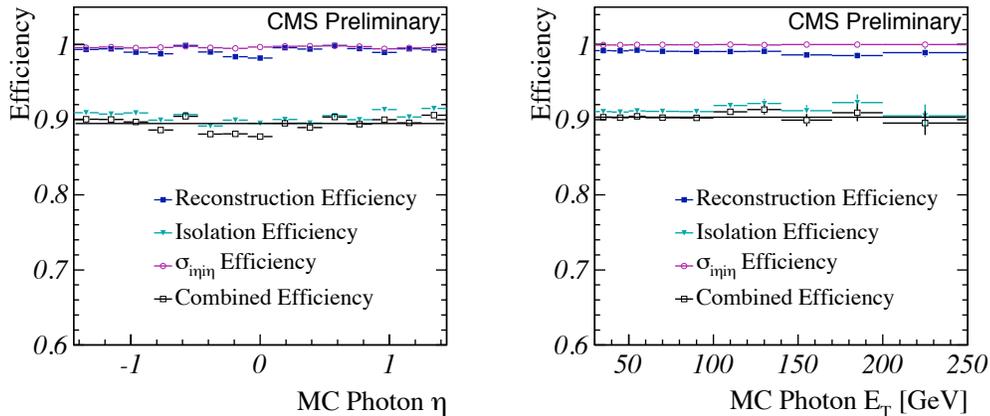

Figure 4.5: Reconstruction, $\sigma_{\text{inn}\eta}$ cut, isolation, and combined efficiency as a function of p_T and η .

1295

1296 4.6 Jet-faking-photon rate

1297 A jet can misidentified as a "fake photon", especially when most of its energy is
 1298 carried by electromagnetic decay particles, for example π_0 . Although jet-faking-
 1299 photon rate (or photon fake rate for short) is small ($\sim 10^{-4}$), the contribution of the
 1300 backgrounds coming from the SM processes associated with jets in the final state
 1301 (e.g., dijets and photon+jets) to photon analysis can be significant due to the high
 1302 cross section of those processes. In this section, a method to estimate the photon fake
 1303 rate is described. The photon fake rate is derived from a photon data set collected
 1304 by single photon trigger paths which contain very loose photons. In this data set, the
 1305 number of photons passing the tight selection in Table 4.3, N_T^{fake} and the number
 1306 of photons passing the loose photon selection N_L^{fake} are found. The loose photon

1307 selection is defined as:

1308 $E_T < 30 \text{ GeV}$

1309 $|\eta| < 1.4442$

1310 $EcalIso < \min(5 \times (4.2 + 0.006 \times p_T), 0.2 \times p_T)$

1311 $HcalIso < \min(5 \times (2.2 + 0.0025 \times p_T), 0.2 \times p_T)$

1312 $TrkIso < \min(5 \times (3.5 + 0.001 \times p_T), 0.2 \times p_T)$

1313 AND

1314 {

1315 $EcalIso > (4.2 + 0.006 \times p_T)OR$

1316 $HcalIso > (2.2 + 0.0025 \times p_T)OR$

1317 $TrkIso > (3.5 + 0.001 \times p_T)OR$

1318 $\sigma_{i\eta i\eta} > 0.013$

1319 } where p_T is in GeV. The photon fake rate is defined as:

$$f_\gamma = \frac{N_T^{fake}}{N_L^{fake}}. \quad (4.1)$$

1320 The denominator photon selection contains an inverted tight photon ID cut which
 1321 is needed to reduce the contamination from direct photons. It can be seen that the
 1322 fake rate is not exactly the probability of a fake photon to be recognized as a tight
 1323 photon which is defined as:

$$p_\gamma = \frac{N_T^{fake}}{N_T^{fake} + N_L^{fake}} \quad (4.2)$$

1324 However, those are related by

$$f_\gamma = \frac{p_\gamma}{1 - p_\gamma} \quad (4.3)$$

1325 The tight photons observed in the data, N_T^{obs} include both N_T^{fake} , which originated
 1326 from jets and direct photons or real photons mostly from photon+jets processes.
 1327 The photon purity, P, which is the fraction of direct photons in N_T^{obs} can be as high

1328 as 70% at $p_T \sim 80$ GeV. The equation Eq. 4.1 is rewritten as:

$$f_\gamma = \frac{N_T^{obs} \times (1 - P)}{N_L^{fake}} \quad (4.4)$$

1329 The contribution of genuine photons to the denominator in Eq. 4.4 is negligible due
1330 to the inverted tight photon ID cut applied.

1331 4.6.1 Photon purity

1332 The photon purity is the fraction of prompt photons in the sample of interest. Here,
1333 the sample of interest contains the tight photons selected by the tight selection in
1334 Section 4.3. The template method is used. The prompt photon templates (the signal
1335 templates), and the fake photon template (the background templates) are provided
1336 as inputs. A binned likelihood fit is performed to find the best fit of those templates
1337 to data.

1338 The shower shape template, $\sigma_{i\eta i\eta}$, is powerful in the signal-background separation.
1339 Therefore, the shower shape method is chosen to get the central values of the purity.
1340 Other template methods, the isolation sum and the conversion methods, are also
1341 considered as cross-checks and discussed later in this section. The prompt photon
1342 templates can be obtained from the photons associated with W or Z bosons in which
1343 the fake photons are reduced significantly by the W or Z selection. With insufficient
1344 events of those processes, we derive the real photon templates from Monte Carlo
1345 (MC) photon+jet samples. The background templates are derived in a background-
1346 enriched region given by inverting the track isolation requirement $2 + 0.001 \times p_T <$
1347 $trackisolation < 4$ GeV. There may be correlation between the shower shape variable
1348 and the track isolation cuts used to define the background-enriched region. This

1349 correlation can affect the correctness in modeling the background templates at the
 1350 signal region. The fit is performed by the `TFractionFitter` method of `ROOT`. The
 1351 `TFractionFitter` is a standard likelihood fit using Poisson statistics. The results of
 the fit are presented in Figure 4.6.

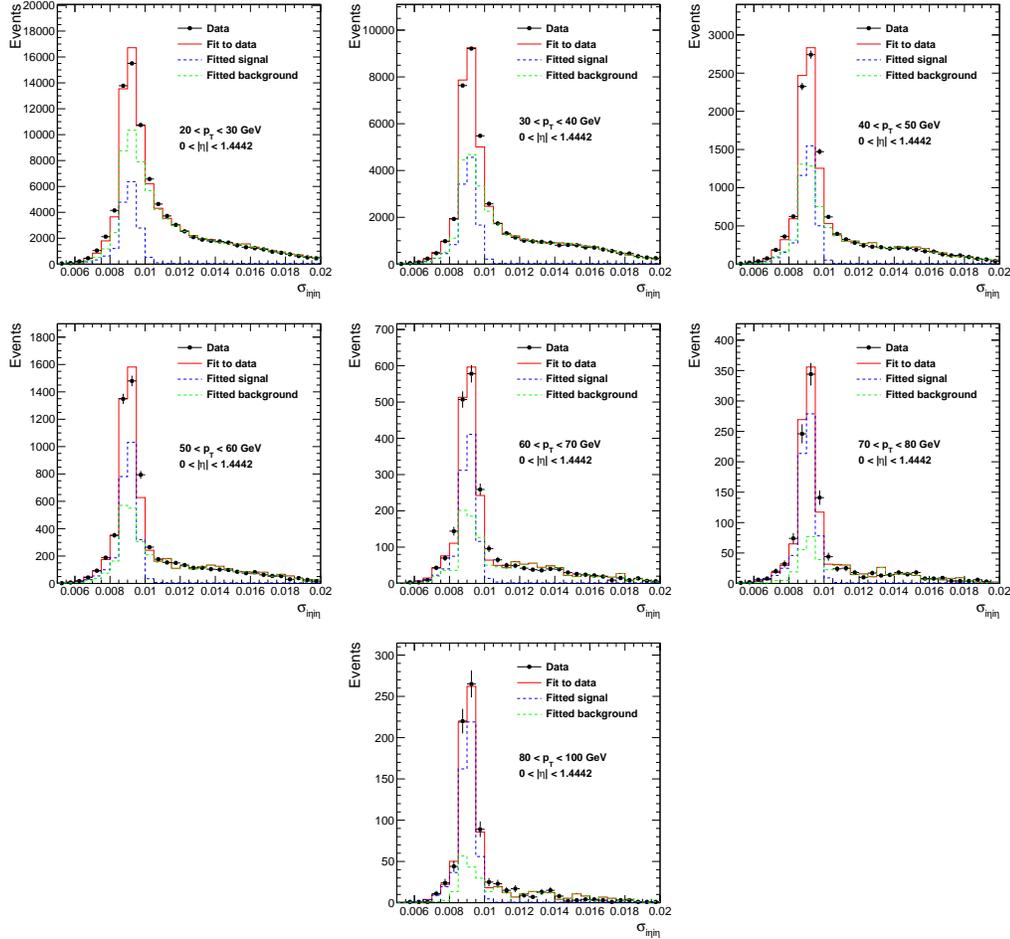

Figure 4.6: σ_{inj} template fit.

1352

1353 The sum of photon isolation is defined as $ISO = ISO_{Ecal} + ISO_{Hcal} + ISO_{Trk}$.
 1354 Here ISO_{Ecal} , ISO_{Hcal} , ISO_{Trk} are the isolation variables in Ecal, Hcal and tracker,
 1355 respectively. This variable is also good in signal-background separation and can
 1356 be used in the template fitting. The signal templates are derived in MC while the
 1357 background templates are obtained from a nearby side-band region, $0.011 < \sigma_{inj} <$

1358 0.013. The main drawback of this method is that the isolation is very sensitive to
 1359 the pile-up effects and the sample used in the purity calculation is different from
 1360 the sample of interest selected by tight selection. The pile-up effects are not well-
 1361 simulated in MC so the difference between a MC signal template and a true data
 1362 template can be significant. The later drawback implies that the calculated purity
 1363 and the purity in the sample of interest may not be the same. Figure 4.7 shows the
 fit results.

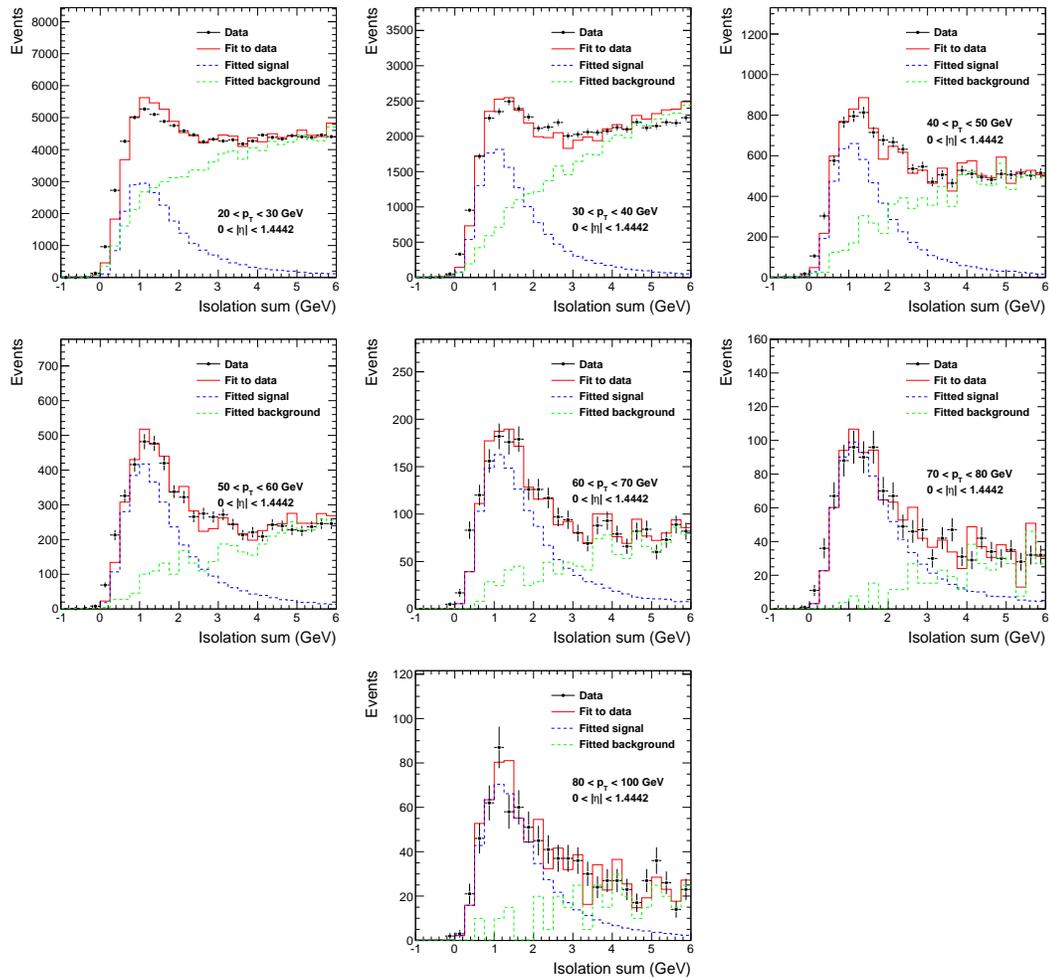

Figure 4.7: Isolation sum template fit.

1364

1365 Finally, our final method is to use converted photons. Two photons are selected
 1366 by requiring that two, oppositely charged tracks associated with corresponding elec-

1367 tromagnetic clusters form a conversion vertex: $|\Delta \cot(\theta)| < 0.05$ and $|\Delta \phi_{vtx}| < 0.1$.
 1368 These photons are required to pass the tight selection. A side-band region of
 1369 $0.011 < \sigma_{i\eta i\eta} < 0.013$ is used to get the background templates. Figure 4.8 shows the
 result of the conversion fits.

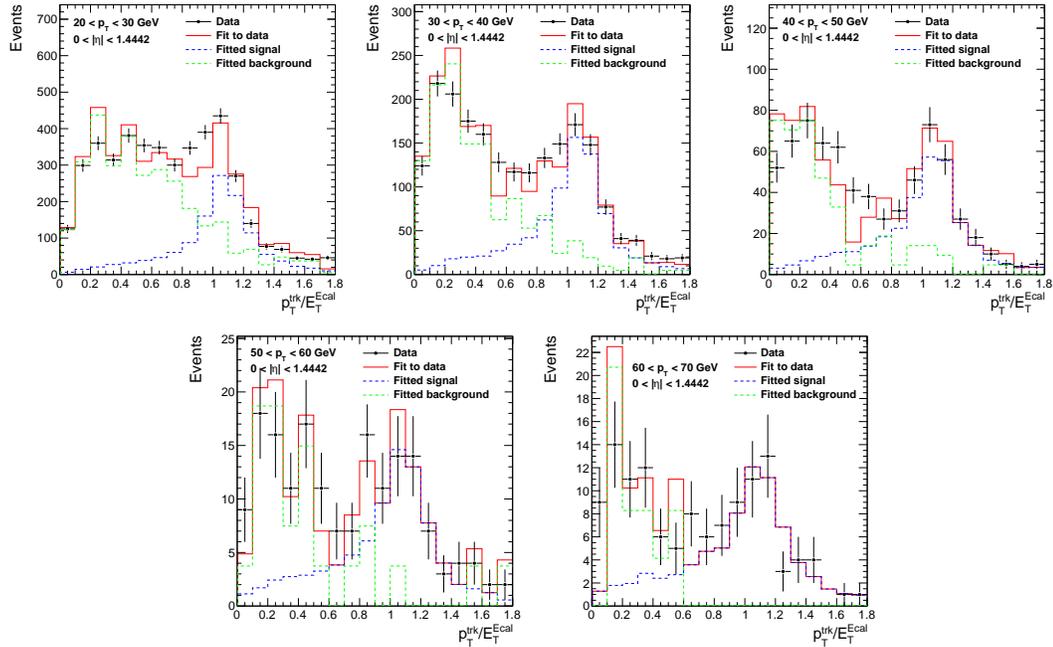

Figure 4.8: Conversion template fit.

1370

1371 4.6.2 Corrected fake rate

1372 By correcting the measured fake rate for the purity as a function of photon E_T ,
 1373 we get the rates shown in Figure 4.9 for each of the template methods. Table 4.4
 1374 shows those rates in numbers. We see that the fake rates from the isolation and the
 1375 conversion methods are within 20% relative with respect to the central values from
 1376 the $\sigma_{i\eta i\eta}$ method.

| E_T bin (GeV) | Shower shape | Isolation sum | Conversion |
|-----------------|-------------------|-------------------|-------------------|
| 20-30 | 0.532 ± 0.009 | 0.491 ± 0.008 | 0.535 ± 0.027 |
| 30-40 | 0.183 ± 0.003 | 0.177 ± 0.003 | 0.205 ± 0.010 |
| 40-50 | 0.128 ± 0.003 | 0.114 ± 0.003 | 0.140 ± 0.011 |
| 50-60 | 0.076 ± 0.002 | 0.067 ± 0.002 | 0.097 ± 0.013 |
| 60-70 | 0.056 ± 0.002 | 0.044 ± 0.002 | 0.068 ± 0.009 |
| 70-80 | 0.033 ± 0.002 | 0.027 ± 0.001 | - |
| 80-100 | 0.030 ± 0.002 | 0.030 ± 0.002 | - |

Table 4.4: Fake rates from shower shape, isolation sum and conversion methods

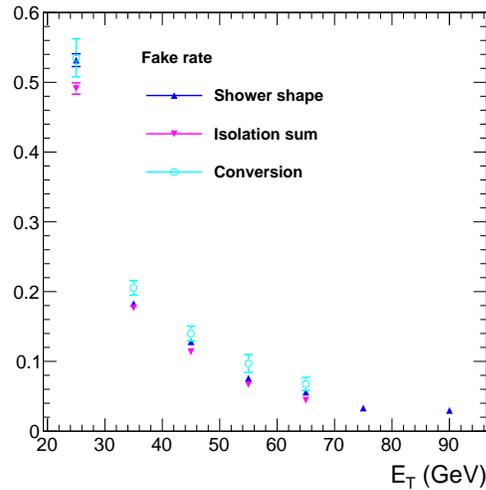

Figure 4.9: Photon fake rate using various methods of correcting for the real photon contamination.

1377 4.6.3 Fake rate and trigger

1378 The single photon triggers are used to get the results in Section 4.6.2. This section
1379 discusses the choice of triggers. The non-isolated HLT triggers in which there is no
1380 any isolation requirement applied to photon trigger objects are chosen. The fake
1381 rate for each trigger with thresholds at 30, 50 and 70 GeV are shown in Figure 4.10.
1382 It can be seen that the fake rate is decreased below the thresholds and above the
1383 trigger thresholds all fake rates are in good agreement. Therefore, the 30, 50 and
1384 70 GeV triggers are used for estimating the fake rate in p_T range 30-50, 50-70 and
1385 above 70, respectively. The fake rates are also derived from the samples selected by

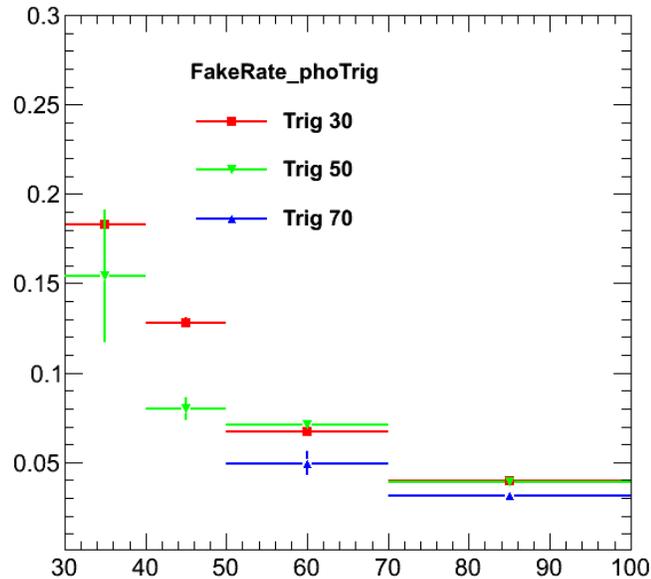

Figure 4.10: Photon fake rates from photon (red), muon (blue) and jet (green) triggers and their ratios to the best fit function.

1386 jet or muon triggers. There are a small discrepancies between the results from those
 1387 triggers. The fake rates of different triggers are then combined in a common fit by a
 1388 function of E_T :

$$p_0 + \frac{p_1}{x^{p_2}} \quad (4.5)$$

1389 The fit results are shown in Figure 4.11. The coefficients found from a best fit are:

$$p_0 = 0.01598, p_1 = 2431.92, p_2 = 2.67771. \quad (4.6)$$

1390 Figure 4.11 also represents the ratio of observed fake rates and the best fit function
 1391 of combined fake rates. From that, a 20% systematic error is assigned to cover the
 1392 variation of observed fake rates.

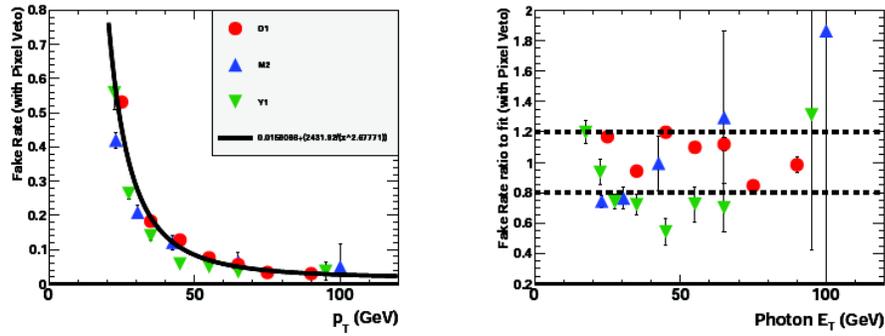

Figure 4.11: Photon fake rates from photon (red), muon (blue) and jet (green) triggers and their ratios to the best fit function.

1393 4.7 Backgrounds

1394 The main sources of backgrounds come from the SM diphoton production, so-called
 1395 diphoton background, and the QCD processes with jets in the final states (dijets,
 1396 photon+jets), so-called QCD background. The SM diphoton background is irre-
 1397 ducible since the events always pass the photon selection and contribute significant
 1398 to the total background especially at the signal region (the high end of the diphoton
 1399 invariant mass spectrum). This type of background is estimated in MC and described
 1400 in Section 4.7.1. The QCD background can be estimated in data-driven manner us-
 1401 ing the photon fake rate, the rate at which a jet fakes as a photon. This background
 1402 is less important than the diphoton background in the signal region given the small
 1403 photon fake rate (10^{-4}). The detail is at Section 4.7.2.

1404 4.7.1 SM diphotons

1405 The SM diphoton background is estimated in MC using PYTHIA generator and
 1406 the full detector simulation by GEANT4. Both contributions from Born and Box
 1407 processes are taken into account. Since these are the tree-level LO contributions,

1408 the K-factor, which is the ratio between LO and NLO cross sections, is applied as
 1409 a scale factor to the diphoton background prediction from PYTHIA. In this analysis,
 1410 we apply a conservative K-factor of 1.3 used by Tevatron experiments. In principle,
 1411 K-factor depends on the center-of-mass energy of hadron-hadron collisions and the
 1412 invariant mass of the diphotons.

1413 We use a dedicated program for diphoton cross section calculation, called DIPHOX [62],
 1414 to study the K-factor of pp collision at 7 TeV. All the LO and NLO diagrams of direct
 1415 and fragmentation processes described in Section 4.5 are implemented in DIPHOX. In
 1416 order to be consistent with photon selection, we limit the η range within $|\eta| < 1.4442$.
 1417 Table 4.5 summarizes the parameter setup. Figure 4.12 shows the LO and NLO
 cross sections and the K-factor as the functions of the diphoton invariant mass.

| Name | Value |
|-----------------------------------|------------|
| PDF | CTEQ6 |
| Type of fragmentation functions | 402 |
| Initial state factorisation scale | 0.5 cm |
| Final state factorisation scale | 0.5 cm |
| Renormalization scale | 0.5 cm |
| $ \eta $ | < 1.4442 |
| p_T | > 30 GeV |
| Radius of isolation cone | 0.4 |

Table 4.5: Parameter setup in DIPHOX for cross section calculation

1418

1419 4.7.2 Dijet and photon+jet

1420 Utilizing the photon fake rate, the dijet and photon+jet backgrounds (QCD back-
 1421 ground) can be estimated by the following method. The events with two photons are
 1422 considered. Among the total number of those events, there are $N_{\gamma\gamma}$ events with two
 1423 real photons, N_{jj} with two fake photons and $N_{\gamma j}$ with one real and one fake photon.

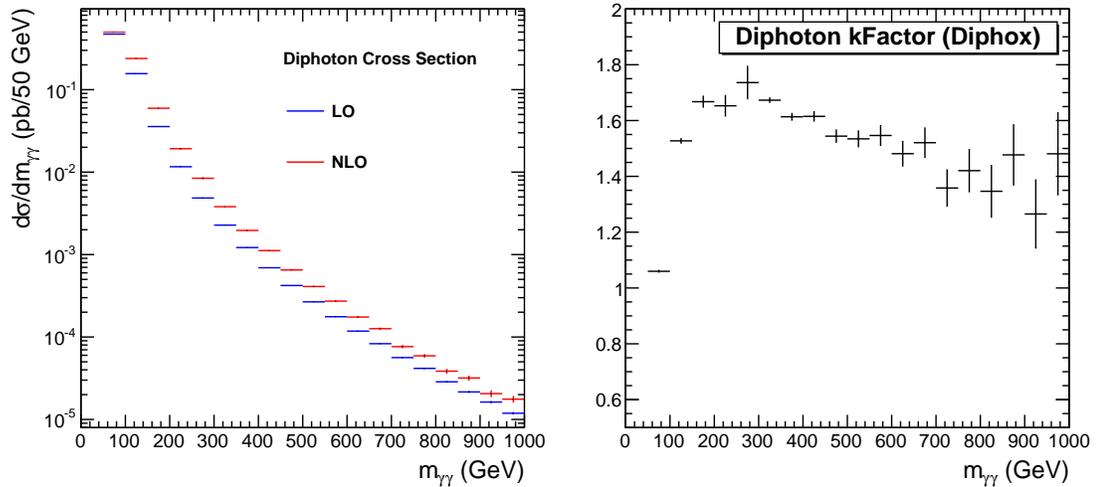

Figure 4.12: The diphoton cross sections (left) and the K-factor (right) from Diphox

1424 If the transverse momenta of photons denoted as x and y , the numbers of events
 1425 in each category are $N_{\gamma\gamma}^{xy}$, N_{jj}^{xy} , $N_{\gamma j}^{xy}$ and $N_{j\gamma}^{xy}$. The ordering of subscripts decides
 1426 which photon has transverse momentum x or y . That is why two combinations for
 1427 the case of one real and one fake photon are needed. An important thing is that
 1428 those numbers of events are not known because the real and fake photons are mixed
 1429 undistinguishable in data. What have been observed instead are the tight (denoted
 1430 T) and the fakeable (denoted F) photons. Therefore, the observed diphoton events
 1431 are N_{TT}^{xy} , N_{FF}^{xy} , N_{TF}^{xy} , N_{FT}^{xy} corresponding to the number of diphoton events with two
 1432 tight, two fakeable and one tight and one fakeable photons, respectively. Again, the
 1433 ordering of the subscript indicates which photons has $E_T = x$ or $E_T = y$. Recalling
 1434 that p_x and p_y are the probability of a photon identified as a tight photon, one can
 1435 write these equations:

$$N_{FF}^{xy} = N_{jj}^{xy}(1 - p_x)(1 - p_y), \quad (4.7)$$

$$N_{FT}^{xy} = N_{jj}^{xy}(1 - p_x)p_y + N_{j\gamma}^{xy}(1 - p_x), \quad (4.8)$$

$$N_{TF}^{xy} = N_{jj}^{xy}p_x(1 - p_y) + N_{\gamma j}^{xy}(1 - p_y), \quad (4.9)$$

$$N_{TT}^{xy} = (N_{jj}^{xy}p_xp_y + (N_{j\gamma}^{xy}p_x + N_{\gamma j}^{xy}p_y) + (N_{\gamma\gamma}^{xy})). \quad (4.10)$$

1436 Solving these equations, the number of diphoton events with two tight photons, which
 1437 is the background to the analysis, can be expressed by observables and probability
 1438 of identifying a tight photon:

$$\begin{aligned}
 N_{TT}^{xy} &= \left(N_{FF}^{xy} \frac{p_x p_y}{(1-p_x)(1-p_y)} \right) \\
 &+ \left(-2N_{FF}^{xy} \frac{p_x p_y}{(1-p_x)(1-p_y)} + N_{FT}^{xy} \frac{p_x}{1-p_x} + N_{TF}^{xy} \frac{p_y}{1-p_y} \right) \\
 &+ (N_{\gamma\gamma}^{xy})
 \end{aligned}$$

1439 The terms in parentheses correspond to the background contributions from di-
 1440 jet, photon+jet and diphoton, respectively. Finally, using Eq. 4.3, we rewrite the
 1441 expression in term of fake rate:

$$N_{TT}^{xy} = (N_{FF}^{xy} f_x f_y) + (-2N_{FF}^{xy} f_x f_y + N_{FT}^{xy} f_x + N_{TF}^{xy} f_y) + (N_{\gamma\gamma}^{xy}). \quad (4.11)$$

1442 Chapter 5

1443 Results and Conclusions

1444 5.1 Data and background prediction

1445 Figure 5.1 shows the diphoton invariant mass spectrum from data and background
1446 estimations. There is no excess of data events over the SM background estimations.
1447 Therefore, no signal of extra dimensions is found and the limit settings are proceeded.
1448 Table 5.1 presents the event counts in different diphoton invariant mass ranges. The
1449 uncertainties in the backgrounds come from 20% photon fake rate systematic un-
1450 certainty. In the signal region, $m_{gg} > 500$ GeV, the predicted SM background is
1451 0.303 ± 0.066 and there is no event observed. The irreducible SM diphoton back-
1452 ground is dominant in this signal region. The kinematic variables of the diphoton
1453 system are plotted in Figures 5.2 and 5.3. The background estimates agrees well
1454 with the number of observed events in those kinematic distributions.

Table 5.1: Data measurements and background expectations for reconstructed diphoton invariant mass ranges. Full systematic uncertainties have been included.

| Process | $60 < M_{\gamma\gamma} < 200$ GeV | $200 < M_{\gamma\gamma} < 500$ GeV | $500 < M_{\gamma\gamma}$ GeV |
|-------------------|-----------------------------------|------------------------------------|------------------------------|
| Dijets | 70 ± 28 | 0.5 ± 0.2 | 0.0009 ± 0.0004 |
| γ +Jets | 145 ± 7 | 2.3 ± 0.3 | 0.016 ± 0.003 |
| Diphotons | 150 ± 35 | 6.2 ± 1.4 | 0.286 ± 0.066 |
| Total Backgrounds | 365 ± 49 | 9.0 ± 1.5 | 0.303 ± 0.066 |
| Observed | 428 | 12 | 0 |

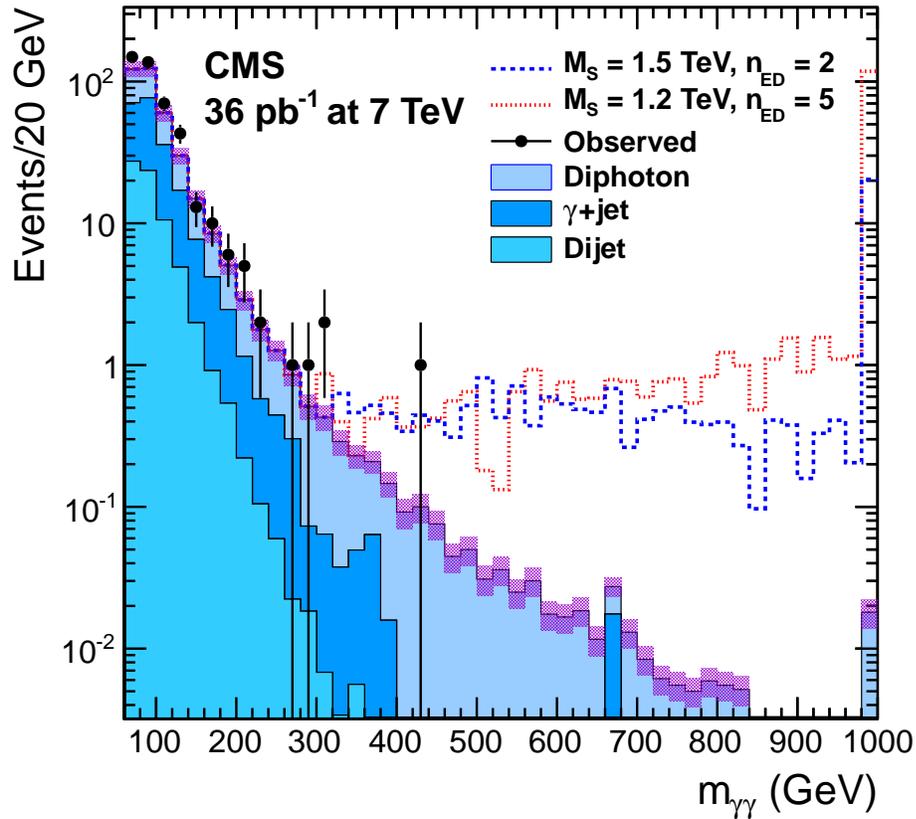

Figure 5.1: Data (points with error bars) and background expectations (filled solid histograms) as a function of the diphoton invariant mass. Photons are required to be isolated, with $E_T > 30$ GeV and $|\eta| < 1.4442$. Also shown with dashed lines the signal for two sets of model parameters.

1455 5.2 Uncertainty

1456 Table 5.2 summarizes the uncertainty of the analysis. The signal efficiency and signal

1457 K-factor uncertainty are described in Section 4.5 and Section 4.7.1. The uncertainty

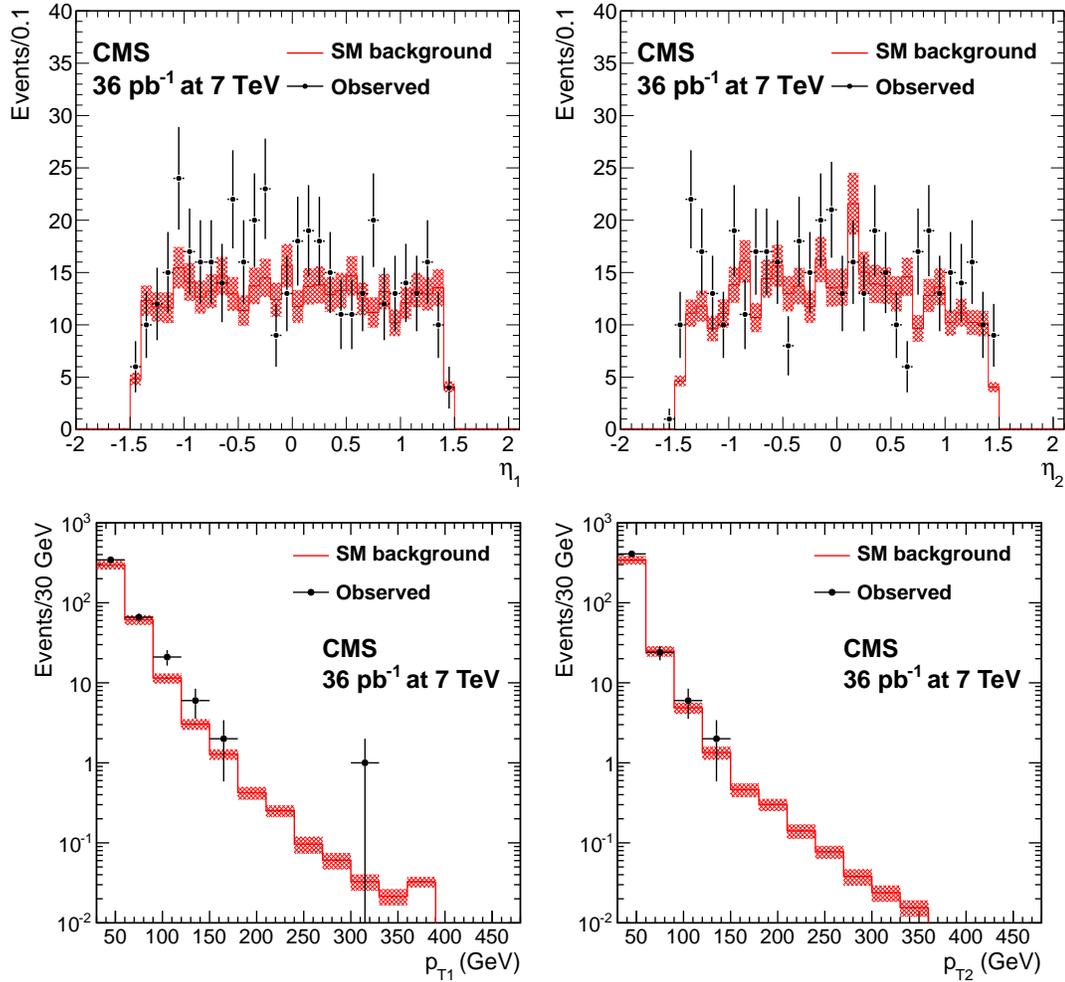

Figure 5.2: Distributions in η and E_T for the leading and sub-leading photons. Points with error bars represent data; the solid histogram corresponds to the expected background.

1458 on the total background is calculated by adding individual background uncertainties
 1459 in quadrature, except for those from the dijet and photon+jet backgrounds since
 1460 they are both induced by the photon fake rate uncertainty. The relative combined
 1461 background uncertainty is 21.8% which is dominated by the diphoton NLO K-factor
 1462 uncertainty.

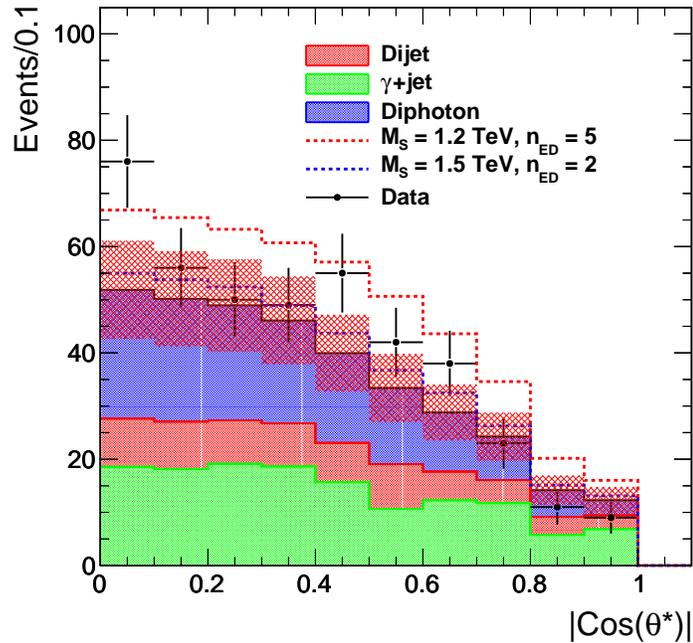

Figure 5.3: Scattering angle in c.o.m. frame of two photons

Table 5.2: Summary of systematic uncertainties.

| | Central Value | Relative Uncertainty |
|----------------------------------|---------------------|----------------------|
| Luminosity | 36 pb ⁻¹ | 4% |
| Background (Diphoton K factor) | 0.30 Events | 23% |
| Signal Efficiency | 77.1% | 6.0% |
| Signal K factor | 1.3 | 7.7% |

1463 5.3 Limit setting method

1464 The standard Bayesian approach is used in the limit setting [63]. Suppose that
 1465 there is a set of parameters (σ, λ) involved in the experiment. σ is the parameter of
 1466 interest, for example cross section and λ is a set of nuisance parameters, for example
 1467 backgrounds, luminosity. The posterior density, $P(\sigma, \lambda|x)$, is related to the prior,
 1468 $\pi(\sigma, \lambda)$, model, $P(\sigma, \lambda|x)$ densities by Bayes' theorem:

$$P(\sigma, \lambda|x) = \frac{P(x|\sigma, \lambda)\pi(\sigma, \lambda)}{\int \int P(x|\sigma, \lambda)\pi(\sigma, \lambda)d\lambda d\sigma} \quad (5.1)$$

1469 x is the observable. The prior density in Eq. 5.1 can be factorized as:

$$\pi(\sigma, \lambda) = \pi(\lambda|\sigma)\pi(\sigma) \quad (5.2)$$

1470 Usually, $\pi(\lambda|\sigma)$ is assumed as $\pi(\lambda)$. The integral over all of the spaces of the nuisance
 1471 parameters is performed and the posterior density in Eq. 5.1 is now a normalized
 1472 function of interested parameter σ . An upper limit, σ^{CL} , is found by:

$$CL = \int_0^{\sigma^{CL}} L(\sigma|x)d\sigma \quad (5.3)$$

1473 In the counting experiment presented in this dissertation, the observable is the num-
 1474 ber of observed events, n and the model density is conventional chosen as the Poisson
 1475 likelihood of observing n events in data given a signal cross section times branching
 1476 fraction times acceptance S , signal efficiency ε , the expected number of background
 1477 events B , and an integrated luminosity \mathcal{L} :

$$P(n|S, \varepsilon, B, \mathcal{L}) = e^{-(B+\varepsilon S\mathcal{L})} \frac{(B + \varepsilon S\mathcal{L})^n}{n!}. \quad (5.4)$$

1478 S is the parameter of interest and the nuisance parameter set includes ε , B and \mathcal{L} .
 1479 A conventional flat prior is chosen for the cross section and the Lognormal functions
 1480 with variance according to the uncertainties of the nuisance parameters are chosen
 1481 as the priors of those. The 95% upper limit on the signal cross section is found by
 1482 solving:

$$\int_0^{S^{95}(n)} L(n|S)dS = 0.95. \quad (5.5)$$

1483 5.4 Limits on the Large Extra Dimension model

1484 Using Table 5.2, the expected upper 95% CL limit on S is 0.118 pb. This limit is
 1485 translated to the limit on the parameters of the ADD model, by the following tech-
 1486 nique. Since the effects of virtual graviton exchange interfere with the SM diphoton
 1487 production, generally, we expect the overall cross section of the diphoton production
 1488 from physics sources to have the following form:

$$\sigma_{\text{ADD}} = \sigma_{\text{SM}} + \eta_G \sigma_{\text{int}} + \eta_G^2 \sigma_{\text{ED}}, \quad (5.6)$$

1489 where η_G is the parameter specifying the strength of ED effects, as discussed in
 1490 Section 1.5. Consequently, after subtracting the σ_{SM} term, the cross section is
 1491 parametrized as a bilinear form in the parameter η_G . For $n_{\text{ED}} = 2$ case, η_G is
 1492 not a constant, as it depends on the invariant mass of the diphoton pair. Therefore,
 1493 in this case the signal cross section is parametrized with a smooth function of $1/M_S^4$.
 The limit on $1/M_S^4$ is found and further translated to the limit on the M_S . The

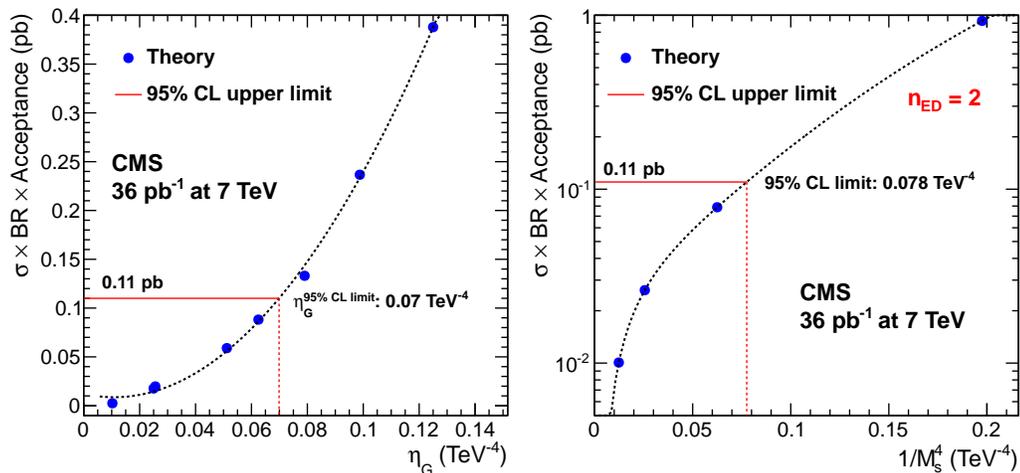

Figure 5.4: Signal cross section parameterization as a function of the strength of the LED, η_G (left) and as a function of $1/M_S^4$ for the $n_{ED} = 2$ case (right).

1494

1495 expected 95% CL limit together with the signal cross section parametrization as a

1496 function of η_G are shown on the left in Figure 5.4. The intersection of the cross sec-
 1497 tion limit with the signal cross section curve determines the upper 95% CL limit on
 1498 the parameter η_G . As seen from the plot, these limits are equal to $\eta_G^{95} = 0.070 \text{ TeV}^{-4}$
 1499 and $1/M_S^4(n = 2, 95\%) = 0.078 \text{ TeV}^{-4}$. The translations to the lower limit on the
 1500 fundamental Planck scale for various numbers of extra dimensions n_{ED} are trivially
 1501 for $n_{\text{ED}} = 2$ and for $n_{\text{ED}} > 2$ by using Eq. (1.18). Table 5.3 shows those limits. The
 1502 limits in convention [32] are identical for $n_{\text{ED}} = 4$ HLZ limits; the limit in Hewett's
 1503 convention with constructive interference is 1.73 TeV and is close to the HLZ limit
 1504 for $n_{\text{ED}} = 5$.

Table 5.3: Table of 95% CL limits on M_S (in TeV), as a function of the convention and number of ED. A comparison of the limits with a truncation of the production cross section above $\sqrt{\hat{s}} > M_S$ is also shown.

| | HLZ | | | | | |
|--------|---------------------|---------------------|---------------------|---------------------|---------------------|---------------------|
| | $n_{\text{ED}} = 2$ | $n_{\text{ED}} = 3$ | $n_{\text{ED}} = 4$ | $n_{\text{ED}} = 5$ | $n_{\text{ED}} = 6$ | $n_{\text{ED}} = 7$ |
| Full | 1.89 | 2.31 | 1.94 | 1.76 | 1.63 | 1.55 |
| Trunc. | 1.80 | 2.23 | 1.84 | 1.63 | 1.46 | 1.31 |
| | GWR | Hewett | | | | |
| | | Pos. | Neg. | | | |
| Full | 1.94 | 1.74 | 1.71 | | | |
| Trunc. | 1.84 | 1.60 | 1.50 | | | |

1505 From the theory construction, the LO signal cross section calculations become
 1506 non-perturbative when the \hat{s} in the $2 \rightarrow 2$ process exceeds M_S^2 . This effect is not
 1507 taken into account in Sherpa cross section calculations used in this analysis, or in
 1508 previous studies of this process at the Tevatron [64], where the effect is not expected
 1509 to be important due to the lower machine energy. Since the energy of the LHC
 1510 is significantly higher than the limits on M_S which can be set in this analysis, it
 1511 is necessarily to take into account this effect by conservatively assuming that the
 1512 signal cross section is zero for $\sqrt{\hat{s}} > M_S$. Under these assumptions the limits on M_S
 1513 decrease by 5% for $n = 2$ (1.8 TeV) and 15% for $n = 7$ (1.31 TeV).

1514 5.5 Conclusions

1515 In conclusion, we have performed a search for large extra dimensions in the diphoton
 1516 final state with a data sample collected in pp collisions at $\sqrt{s} = 7$ TeV correspond-
 1517 ing to an integrated luminosity of 36 pb^{-1} . We optimize the signal selection to reach
 1518 maximum sensitivity in a counting experiment in a one-sided mass window by se-
 1519 lecting events with centrally produced photons ($|\eta| < 1.4442$) and large diphoton
 1520 invariant mass ($m_{\gamma\gamma} > 500$ GeV). We estimate the SM backgrounds and compare
 1521 with the observed data. Given the absence of an excess over the SM prediction, we
 1522 set lower limits on the cutoff scale M_S in the range 1.6-2.3 TeV. These results extend
 1523 the current limits reached at the Tevatron in all but the $n_{ED} = 2$ case.

1524 In addition to setting limits on a specific model of large extra dimensions, a
 1525 model-independent limit on any new physics mode which results in central, high
 1526 p_T diphotons - either resonant or non-resonant (e.g. Kaluza-Klein gravitons in the
 1527 Randall-Sundrum model [65]) is quoted. It is that a 95% C.L. exclusion on the cross
 1528 section times branching fraction times acceptance of 118 fb is set for diphoton pairs
 1529 with $M_{\gamma\gamma} > 500$ GeV and the following kinematic requirements on each of the two
 1530 photons: $p_T > 30$ GeV and $|\eta| < 1.4442$.

1531 While this analysis was being finalized, a phenomenological interpretation of
 1532 the dijet angular distribution results from the CMS and ATLAS experiments ap-
 1533 peared [66] and suggested even stronger limits on M_S . However, a dedicated exper-
 1534 imental analysis and interpretation of the dijet data in the models with large extra
 1535 dimensions has yet to be conducted.
